After doing this, however, a bump or lump is formed. I will endeavor to tell you how the bump is formed or rather what causes it to form. You cannot knock your head against anything that is harder than your head without causing some injury to the parts which received the bump. Now, what happens then is just what happens to any other part of your body when it is injured whether as a result of a bump, a cut or a bee or mosquito sting.

As soon as the injury occurs the brain starts the “repair crew” to work. The result is that first a great supply of blood is rushed to the injured part with the result that the blood vessels are filled up and extended with blood. Certain parts of the blood cells find their way through the walls of the blood vessels at the part of the injury and other fluids from the body are piled up there, so to speak, to form a congestion. This “piling up or congestion” distends the skin and raises the bump. On the head where the layer of muscular structure is thinner and where there is less space between the bones of the skull and the outside skin, the bump will be larger and more noticeable, because a good deal of blood and other fluids are piled up in a comparatively small space, and so the skin gets pushed out further to accommodate this great congestion, whereas in other parts of the body the bump may be quite as large but not so noticeable.

[Illustration: PUTTING ON THE IRON-SOLED SHOES.

They are purposely made heavy, to help the diver sink.]

The Deep Sea Diver

What Does the Bottom of the Sea Look Like?

It looks very much like the land on which we live. There are mountains and valleys, rocks and crags, trees and grass, just the same as we see on land, except, of course, that there are no human beings to be seen. Instead of birds flitting about the tree-tops, fish swim about them, and where the squirrel and rabbit bound through the woods on land, the great king crab and sea turtle drag their unwieldy forms on the ocean’s bottom. Some of the scenes at the bottom of the sea are like fairyland, and in tropical waters are

often as beautiful and spectacular as those we see in theatrical pantomimes. Delicately tinted sea-shells, great trees of snow-white coral, sea foliage of every tint and shape, and deep dark caverns, in which lurk the devil-fish and other odd looking fish.

The Diver's Outfit.

The armor of to-day consists of a rubber and canvas suit, socks, trousers and shirt in one, a copper breastplate or collar, a copper helmet, iron-soled shoes, and a belt of leaden weights to sink the diver.

[Illustration: ADJUSTING THE TELEPHONE.

This enables the diver to talk at all times to those above him.]

[Illustration: PUTTING ON THE HELMET.

It is made of tinned copper, with three glass-covered openings, to enable the diver to look out.]

[Illustration: TELEPHONING FROM THE BOTTOM OF THE OCEAN

TESTING THE TELEPHONE.

Every precaution is taken to see that everything is in order before the diver goes down.]

[Illustration: THE FINAL TEST.

The least error in the adjustment may mean death to the diver.]

The helmet is made of tinned copper, with three circular glasses, one in front and one on either side, with guards to protect them. The front eye-piece is made to unscrew and enable the diver to receive or give instructions without removing the helmet. One or more outlet valves are placed at the back or side of the helmet to allow the vitiated air to escape. These valves only open outwards by working against a spiral spring, so that no water can enter. The inlet valve is at the back of the helmet, and the air on entry is directed by three channels running along the top of the helmet to points above the eye-pieces, enabling the diver to always inhale fresh air. The helmet is secured to the breastplate below by a segmental screw-bayonet joint, securing attachment by one-eighth of a turn. The junction between the water-proof dress and the breastplate is made watertight by means of studs, brass plates and wing-nuts.

A life or signal-line and also a modern telephone enables the diver to communicate at all times with those above him.

The cost of a complete diving outfit ranges from $750.00 to $1,000.00. The weight of the armor and attachments worn by the diver is 256 pounds, divided as follows: Helmet and breastplate, 58 pounds; belt of lead weights, 122 pounds; rubber suit, 19 pounds; iron-soled shoes, 27 pounds each.

The air which sustains the diver's life below the surface is pumped from above by a powerful pump, which must be kept constantly at work while the diver is down. A stoppage of the pump a single instant while the diver is in deep water would result almost in his instant death from the pressure of the water outside.

The greatest depth reached by any diver was 204 feet, at which depth there was a pressure of 88½■ pounds per square inch on his body. The area exposed of the average diver in armor is 720 inches, which would have made the diver at that depth sustain a pressure of 66,960 pounds, or over 33 tons.

The water pressure on a diver is as follows:

20 feet 8½■ lbs. 30 feet 12⅜■ lbs. 40 feet 17½■ lbs. 50 feet 21⅜■ lbs. 60 feet 26½■ lbs. 70 feet 30½■ lbs. 80 feet 34⅜■ lbs. 90 feet 39 lbs. 100 feet 43½■ lbs. 120 feet 52½■ lbs. 130 feet 56½■ lbs. 140 feet 60⅜■ lbs. 150 feet 65½■ lbs. 160 feet 69⅜■ lbs. 170 feet 74 lbs. 180 feet 78 lbs. 190 feet 82½■ lbs. 204 feet 88½■ lbs.

The dangers of diving are manifold, and so risky is the calling that there are comparatively few divers in the United States. The cheapest of them command $10.00 a day for four or five hours' work, and many of them get $50.00 and $60.00 for the same term of labor under water.

The greatest danger that besets the diver is the risk he runs every time he dives of rupturing a blood-vessel by the excessively compressed air he is compelled to breathe. He is also subject to attacks from sharks, sword-fish, devil-fish, and other voracious monsters of the ocean's depths. To defend himself against them, he carries a double-edged knife as sharp as a razor. It is the diver's sole weapon of defense.

Just how far back the art of submarine diving dates is a matter of conjecture, but until the invention of the present armor and helmet, in 1839, work and exploration under water was, at best, imperfect, and could only be pursued in a very limited degree.

Feats of Divers.

~THE GREATEST DIVING FEAT~

Millions of dollars' worth of property has been recovered from the ocean's depth by divers. One of the greatest achievements in this line was by the famous English diver, Lambert, who recovered vast treasure from the "Alfonso XII," a Spanish mail steamer belonging to the Lopez Line, which sank off Point Gando, Grand Canary, in 26½■ fathoms of water. The salvage party was dispatched by the underwriters in May, 1885, the vessel having £100,000 in specie on board. For nearly six months the operations were persevered in before the divers could reach the treasure-room beneath the three decks. Two divers lost their lives in the vain attempt, the pressure of water being fatal. The diver recovered £90,000 from the wreck, and got £4,500 for doing it.

One of the most difficult operations ever performed by a diver was the recovering of the treasure sunk in the steamship "Malabar," off Galle. On this occasion the large iron plates, half an inch thick, had to be cut away from the mail-room, and then the diver had to work through nine feet of sand. The whole of the specie on board this vessel--upward of $1,500,000--was saved, as much as $80,000 having been gotten out in one day.

It is an interesting fact that from time to time expeditions have been fitted out, and companies formed, with the sole intention of searching for buried treasure beneath the sea. Again and again have expeditions left New York or San Francisco in the certainty of recovering tons of bullion sunk off the Brazilian coast, or lying undisturbed in the mud of the Rio de la Plata.

[Illustration: The last look just before going down.]

[Illustration: Coming up after a successful trip.]

At the end of 1885, the large steamer Imbus, belonging to the P. & O. Co., sank off Trincomalee, having on board a very valuable East-India cargo, together with a large amount of specie. This was another case of a fortune found in the sea, for a very large amount of treasure was recovered.

Another wreck from which a large sum of gold coin and bullion was recovered by divers, was that of the French ship "L'Orient." She is stated to have had on board specie to the value of no less than $3,000,000, besides other treasure.

A parallel case to "L'Orient" is that of the "Lutine," a warship of thirty-two guns, wrecked off the coast of Holland. This vessel sailed from the Yarmouth Roads with an immense quantity of treasure for the Texel. In the course of the day it came on to blow a heavy gale; the vessel was lost and went to pieces. Salvage operations by divers, during eighteen months, resulted in the recovery of £400,000 in specie.

Humorous scenes do not play much of a part on the ocean's bottom, and the sublime and awe-inspiring are far more in evidence there than the ludicrous, yet even beneath the waves there are laughable scenes at times. A diver had been engaged to inspect a sunken vessel off the coast of Cuba. Arriving on the scene he discovered a number of native sponge-divers, who descend to considerable depths, diving down from their canoes to the sunken vessel trying to pick up something of value. They paid little attention to the arrival of the wrecking outfit, and did not notice the diver descend, until suddenly what seemed to them to be a horrible human-shaped monster, with an immense head of glistening copper and three big, round, glassy eyes, came walking around the vessel's bow and made a big salaam to them. That was enough. They shot surfaceward like sky-rockets, climbed frantically into their canoes and hurriedly rowed away.

What Happens When Anything Explodes?

By explosives are meant substances that can be made to give off a large quantity of gas in an exceedingly short time, and the shorter the time required for the production of the gas the greater will be the violence of the explosion. Many substances that

ordinarily have no explosive qualities may be made to act as explosives under certain circumstances. Water, for example, has caused very destructive boiler explosions when a quantity of it has been allowed to enter an empty boiler that had become red hot. Particles of dust in the air have occasioned explosions in saw mills, where the air always contains large quantities of dust. A flame introduced into air that is heavily laden with dust may cause a sudden burning of the particles near it, and from these the fire may be conveyed so rapidly to the others that the heat will cause the air to expand suddenly, and this, together with the formation of gases from the burning, will cause an explosion.

It must not be thought, however, that fine sawdust or water would ordinarily be classed as explosives. The term is generally applied only to those substances that may be very easily caused to explode.

The oldest, and most widely known, explosive that we possess is gunpowder, the invention of which is generally credited to the Chinese. It is a mixture of potassium nitrate, or saltpeter, with powdered charcoal and sulphur. The proportions in which these substances are mixed vary in different kinds of powder, but they usually do not differ much from the following:

Sulphur 10 per cent. Charcoal 16 per cent. Saltpeter 74 per cent.

The explosive quality of gunpowder is due to the fact that it will burn with great rapidity without contact with the air, and that in burning it liberates large volumes of gas. When a spark is introduced into it, the carbon, charcoal, and sulphur combine with a portion of the oxygen contained in the saltpeter to form carbonic acid gas and sulphurous acid gas, and at the same time the nitrogen contained in the saltpeter is set free in the gaseous form. This action takes place very suddenly, and the volume of gas set free is so much greater than that of the powder that an explosion follows.

In the manufacture of gunpowder all that is absolutely necessary is to mix the three ingredients thoroughly and in the proper proportions. But to fit the powder for use in firing small arms and cannon it is made into grains of various sizes, the small sizes being used for the small arms with short barrels, and the large sizes for cannon. The reason for this is that if the powder is made in very small grains it all burns at once, and the explosion takes place so suddenly that an exceedingly strong gun is required to withstand the explosion, while if larger grains are employed the burning is slower and continues until the projectile has traveled to the muzzle of the gun. In this way the projectile is fired from the gun with as much force as if the explosion had taken place at once, but there is less strain on the gun.

What Causes the Smoke When a Gun Goes Off?

Powder of this latter kind always produces a considerable quantity of smoke when it is fired, because there is a quantity of fine particles formed from the breaking up of the saltpeter and from some of the charcoal which is not completely burned. This smoke forms a cloud that takes some time to clear away, which is a very objectionable feature. In order to get rid of it, efforts were made to produce a substance that would explode without leaving any solid residue, and that could be used in guns. These efforts were finally successful, and there are now several brands of smokeless powder in use.

What is Smokeless Powder Made Of?

The most satisfactory forms of smokeless powder are all made from guncotton or nitrocellulose. This substance, which is made by treating cotton with a mixture of nitric and sulphuric acids, is a chemical compound, not a mixture like gunpowder; and when it is exploded it is all converted into gases, of which the chief ones are carbonic acid gas, nitrogen, and water-vapor. To cause the explosion of guncotton it is not necessary to burn it, but a mere shock or jar will cause it to decompose with explosive violence. Of course, such a violent explosive as this could not be used either in small arms or in cannon, but guncotton can be converted into less explosive forms which are suitable for use in guns, and the majority, of smokeless powders are made in this way. The methods used in producing the smokeless powders are kept secret by the various countries that use them.

What is Nitroglycerine?

Another very powerful explosive, which is closely related to guncotton, is nitroglycerine. This compound is made by treating glycerine with the same sort of acid mixture that is used in making guncotton. It explodes in the same way that guncotton does and yields the same products. It is an oily liquid of yellow color, and on account of its liquid form it is difficult to handle and use. The difficulty in handling nitroglycerine led to the plan of mixing it with a quantity of very fine sand called infusorial earth. When mixed

with this a solid mass called dynamite is formed, which is easier to handle and more difficult to explode, but which has almost as much explosive force as nitroglycerine.

A more powerful explosive than either nitroglycerine or guncotton is obtained by mixing them together. When this is done the guncotton swells up by absorbing the nitroglycerine and becomes a brownish, jelly-like substance that is known as blasting gelatin. This is generally considered the most powerful explosive obtainable.

What Makes Nitroglycerine and Guncotton Explode So Readily?

Let us now consider for the moment what it is that makes guncotton, nitroglycerine, and blasting gelatin explode so readily. The explanation is found in the presence in them of nitrogen. As you remember from what you learned about air, nitrogen is an extremely inactive element. It has no strong tendency to combine with other elements, and when it does enter into combination with them the compounds formed are almost always easily decomposed. In the compounds that have just been described a shock causes a loosening of the bonds that hold the nitrogen, and the whole compound goes to pieces just as an arch falls when the keystone is removed.

What Is Silver?

Since the earliest time recorded in history, silver has been the most used of the precious metals, both in the arts and as a medium of exchange. Even in the prehistoric times silver mines were worked and the metal was employed in the ornamental and useful arts. It was not so early used as money, and when it began to be adopted for this purpose, it was made into bars or rings and sold by weight. The first regular coinage of either gold or silver was in Phrygia, or Lydia, in Asia Minor. Silver was used in the arts by the Athenians, the Phœnicians, the Vikings, the Aztecs, the Peruvians, and in fact by all the civilized and semi-civilized nations of antiquity. It is found in almost every part of the globe, usually in combination with other metals. The mines in South America, Mexico, and the United States are especially rich. Silver is sometimes found in huge nuggets. A mass weighing 800 pounds was found in Peru, and it is claimed that one of 2,700 pounds was extracted in Mexico. The ratio of the value of silver and gold has varied greatly. At the Christian era it was 9 to 1; 500 A.D. it was 18 to 1; but in 1100 A.D. it was only 8 to 1. In 1893 it was as high as 2,577 to 1. The subject has entered largely into American politics as a disturbing element, and in 1896 the Democratic party, in its national convention, declared for the free coinage of the metals at 16 to 1. The Republican party adhered to the gold standard and declared against the free coinage of silver. Each party reaffirmed in 1900 this plank in its platform. In both years the Democrats were defeated.

What Is Worry?

Worry is a feeling of fear, but is never of the present. It is always about something that may happen or that has happened. It is generally in the future, sometimes in the past, but never in the present.

An animal that knows neither future nor past cannot worry. Babies, living only as they do in the present, cannot worry. All creatures, excepting human beings, live only in the present and therefore they do not worry, for such creatures cannot remember what happened in the past or guess what is going to happen.

A human being after arriving at a certain age is given such powers that his mind can go back to the past and cast itself forward into the future as he thinks it will be, because he has imagination. As a matter of fact we live less in the present than in the past or future.

Why Do We Worry?

We worry because we are able through a power called self-consciousness to place ourselves through our minds for the time being. Either--back somewhere in the past without carrying our physical bodies with us; for if we could take our bodies with us, we would be in the present again, and then worry is impossible; or, we use our imagination and project the future entirely apart from our bodies, for we cannot project our bodies into the future, and if we could we would again be in the present. We worry over going to have an operation performed which may or not be dangerous, but quite necessary. We may still think we worry when the operation begins, but as soon as that occurs the time becomes the present, and though we may fear, we cannot worry in the present.

Back View of Shield

Longitudinal Section through Shield & Tunnel

Diagram showing method of tunnel construction by shield and compressed air.

Scale; ½■ inch · 1 foot

Jacobs & Davies Inc. 30 Church St. N.Y.

Oct. 15. 1910.

FIGURE 1.]

The Story in a Tunnel

How a Tunnel Is Dug Under Water.

Fig. 1. On the left is a cross section showing, in diagram, the back view of a shield. The heavy black circle is the “tail” or “skin.” The small circles within the tail are the hydraulic rams which at a pressure of 5,000 pounds to the square inch force the shield forward. The square compartments within the shield are the openings through which the men pass to dig away the ground. In the middle of the shield is shown the swinging “erector” which picks up the iron lining plates and puts them in position.

The view on the right is a longitudinal section of the tunnel showing the shield and the bulkhead wall across the tunnel with the air locks built into it. The front of the shield ahead of the doors is made with a sharp edge called the “cutting edge” and this makes it easier for the shield to advance in case all the ground in front has not been removed. This view shows how the tail overlaps the last portion of the iron lining.

Some distance behind the shield comes the concrete bulkhead wall with the air locks contained in it. There are two shown in the view. The upper one is the emergency air lock, always kept ready so that in case of an accident the men have a means of escape even though the lower part of the tunnel is filled with rushing water or mud. The lower air lock is for the passage of men and materials during ordinary working. This view also shows that all the tunnel ahead of the bulkhead wall is under compressed air while the finished tunnel behind the bulkhead wall is under the ordinary or normal air pressure. When the tunnel is finished the air locks and bulkhead walls are removed.

[Illustration: FRONT VIEW OF A DRIVING SHIELD

This shows the front of one of the shields used on the Pennsylvania Railroad tunnels crossing the North River at New York. The cutting edge is clearly seen and the various compartments, each with its door, which divide up the front of the shield. These shields weighed about 200 tons each.]

HOW TUNNELS ARE BUILT.

These notes describe very generally the way in which tunnels are built through mud and gravel under parts of the sea or large rivers in such a way that the men who build them are protected and as safe as the carpenter who is building a house.

The way these tunnels are built is called the “shield” way because the machine used is called a shield. It is given this name because it shields the tunnel builders from the water and the mud which are ready at every moment to overwhelm them and kill them.

The shield was invented in 1818 by a great Engineer, Marc Isambard Brunel, who was a Frenchman living in England. The idea of the shield came to him as he saw how the sea worm which attacks the wooden piles of docks along the shore bores the holes it makes in the wood. The head of this worm is very hard and can bite its way through the hardest woods. As it goes through the wood its body makes a hard shelly coating which lines the holes which its head has made and prevents the hole from getting filled up. This is the general idea of a tunnel built by a shield.

The first shield was used by Mr. Brunel to make a tunnel across the Thames River at London, England. This is still the biggest tunnel ever built by a shield, although not the longest, and is still used by railroad trains. This tunnel was begun in 1825 and was finished in 1843, and provides a history of almost unexampled and not-to-be-excelled courage in attacking difficulties and skill in defeating them.

Since the days of Brunel many great improvements have been made in the shield and in the way of working it but the same idea is still there.

[Illustration: HOW THE SHIELD IS PUSHED FORWARD

This shows the rear end or tail end of one of the smaller shields, used on the Hudson and Manhattan Railroad tunnels under the North or Hudson River at New York. It shows the skin, the hydraulic jacks within the skin and the piping and valves for working them. It also shows the doors leading to the front or “face.” The erector is not shown, but the circular hole in the middle shows where it would be attached.]

[Illustration: This shows one side of an air lock bulkhead wall with the air lock in place. The boiler-like appearance of the lock is clearly visible, as well as the door and the pressure gauge to tell the air pressure inside the lock.]

[Illustration: This is a rear view of one of the Pennsylvania Tunnel shields, taken after a length of tunnel had been completed. All the details of construction are shown, but in this case the erector is clearly seen also. The valves which control the erector and the rams which push the shield forward are seen near the top of the shield. The rods across the tunnel are turn-buckles used to keep the iron lining from getting out of shape in the soft mud. These are removed later. The floor and tracks in the bottom are temporary and are used for bringing materials to and from the shield.]

After the days of Brunel’s shield another great help was given to tunnel builders by the invention of the use of compressed air to hold back the water which saturates the ground in which the tunnel is being built.

~WHO INVENTED THE COMPRESSED AIR METHOD~

The first real invention of compressed air for this purpose was made by Admiral Sir Thomas Cochrane who, in 1830, took out a patent for the use of compressed air to expel the water from the ground in shafts and tunnels and, by this means, to convert the ground from a condition of quicksand to one of firmness. This patent covers all the essential features of compressed air working.

As suggested above, the thing which compressed air does in a tunnel is to push the water out from all the spaces which it fills in the ground, so that the men who are digging away the ground for the tunnel are working in firm dry ground instead of a mixture of earth and water which will run into and fill the hole they dig as soon as it is dug.

Whenever a tunnel is being built below a body of water through ground which is porous, or in other words through any ground except solid rock or dense clay, the water fills every crevice and space in the ground and is exerting a pressure of about half a pound per square inch above the ordinary pressure of the air, (which is 15 pounds to the square inch) for every foot of depth below the surface of the water; so that supposing the tunnel is 40 feet below the water the water has a pressure of nearly 20 pounds per square inch on every square inch of the surface of the tunnel. This pressure causes the water to flow violently into any hole or opening that is made in the ground, and, unless the water is prevented from moving by some means or other, the opening made would be very quickly filled with water and also with ground as the rush of water will carry the sand, gravel or mud with it.

By Cochrane’s invention the whole tunnel is filled with air under a pressure equal to the pressure of the water. This compressed air therefore balances the pressure of the water and holds it back from moving, and if the pressure of the air is made slightly greater than that of the water the water is driven back from the tunnels for a short distance so that when the tunnel is being dug the ground instead of being wet is quite dry.

This explains the principles of the shield and compressed air way of making a tunnel.

The following describes very shortly how these principles are put to actual use.

Most tunnels which are built by shield and compressed air under rivers or arms of the sea are lined with cast iron plates to protect the railway or roadway which is in the tunnel.

The tunnel is a circular tube, or shell, and the plates have flanges on all sides which are bolted together. This shell is put into place, plate by plate, by means of the shield which not only protects the workmen and the work under construction, but which helps to build the iron shell. In fact it corresponds to the sea worm which bores through the wood and lines the hole with a shell. In the case of the tunnel the shell is made of iron. The shield itself consists of a steel tube or cylinder slightly bigger in diameter than the tube or tunnel it is intended to build. The front edge of this shield is made up of a ring of sharp edged castings which form what is called the “cutting edge.” Just behind the cutting edge is a bulkhead or wall of steel, in which are openings which may be opened or closed at will. Behind this bulkhead are placed a number of hydraulic jacks or presses arranged around the shield and within it, so that by thrusting against the last erected ring of iron lining the whole shield is pushed forward. The rear end of the shield is a continuation of the cylinder which forms the front end, and this part, called the “tail,” always overlaps the last few feet of the built up iron shell.

[Illustration: This is a photograph of a model of the Pennsylvania Tunnels to New York City, made for the Jamestown Tercentenary Exposition of 1907. It is given because it illustrates, as no photograph of actual work could do, the relationship between the shield, the tunnel itself and the air lock. This view shows the rear part of the shield on the extreme left, with the erector picking up an iron plate. It shows a man bringing a car with two of the iron plates up to the shield. Behind this man comes the bulkhead wall with the emergency air lock in the top and the ordinary air lock for passing in and out at the bottom. It also shows the upper platform to the emergency lock along which the men can get to the emergency lock in case of an accident.]

[Illustration: This is another view of the same model, but showing the front view of the shield. The doors on the air locks are clearly shown.]

[Illustration: This is a photograph taken in one of the Pennsylvania tunnels under the Hudson River. It shows the soft mud, through which the tunnel is being built, flowing in a thick stream through one of the doors of the shield. The mud under the Hudson, where these tunnels are, is so soft that often the shield was pushed through the mud with all the doors shut, so that no mud came into the tunnel and no digging had to be done, but the shield pushed its way bodily through the mud, the rings of iron lining being built up behind as usual. Generally, however, a certain amount of mud was brought in and had to be removed. This photograph shows how it looked.]

~HOW THE SHIELD CUTS THROUGH THE GROUND~

The diagram, Fig. 1, shows more clearly what is meant. From an inspection of Figure 1 it is clear that, when the openings in the shield bulkhead are closed, the tunnel is protected from an inrush of either water or earth; the openings in the bulkhead may be so regulated that control is maintained over the material passed through. After a ring of iron lining has been erected within the tail of the shield, the shield doors are opened and men go through them and dig out enough earth for the shield to go ahead. The rams are then thrust out thus pushing the shield ahead. Another ring of iron is built up within the tail for which purpose an hydraulic swinging arm, called the “erector,” is mounted on the shield face. This erector picks up the plates and puts them into position, one by one, while the men bolt them together. Excavation is then carried on again and the whole round of work repeated, gaining every time the jacks are rammed or thrust out a length equal to the length of one ring of iron lining. In carrying out this work in ground charged with water the shield is assisted by introducing compressed air as described before. To use the compressed air thick bulkhead walls of masonry are built across the tunnel behind the shield and into the space between the shield and the bulkhead wall air is pumped, compressed to the same pressure as that of the water in the ground, or in other words the pressure of the air in pounds per square inch is about half the number of feet the tunnel is below the water surface. This dries the ground and simplifies enormously the difficulty of working in it. The diagram, (Fig. 1) shows a bulkhead wall across the tunnel. In order to pass from the ordinary air outside the bulkhead into the compressed air inside it, all the men and the materials have to pass through the “air locks” which are built into the wall. They are called air locks because they are like the locks on a canal which raise the water from a lower to a higher level or lower it from a higher to a lower level as the case may be. The difference is that an air lock enables one to pass from air at a low pressure to one of a higher, or vice versa. An air lock is made like a large boiler with a door at each end. If we wish to enter the compressed air we enter the lock from the outside. The door at the end has been tightly closed to prevent the compressed air from rushing out. We close the door behind us and are now tightly shut in the boiler-like lock. We now open a valve and compressed air begins to flow quickly into the air lock and the air gets hotter and hotter, due to the compression of the air. Very likely an intense pain begins to make itself felt in the ears but by swallowing hard and blowing the nose it may be relieved. It is caused by the air pressure being greater on the outside of the ear drum than on the inside. If the delicate ear passages are choked, because of a cold or some such reason, it is unsafe to go further or the ear drum may burst. When the pressure in the air lock has reached that in the working chamber, the door leading to the shield may be opened and we can pass to the working space and note the work going on. There is no especial bodily sensation to be felt except a slight exhilaration and it is curious to find that one

cannot whistle. On leaving the compressed air we enter the air lock by the door we left; a valve is turned and the air begins to escape and the pressure in the air lock begins to go down. As it does so the air becomes colder and colder and the whole lock is filled with a wet fog due to the chilling by expansion of the air. The air has to be allowed to escape very slowly, as bubbles of air and gas otherwise form in the blood vessels and tissues of the body giving rise to the very painful complaint known to tunnel builders as “the bends,” and in very serious cases to paralysis and even death. The higher the air pressure the more slowly must one come out into the ordinary air.

[Illustration: MAKING THE JOINTS WATER TIGHT

This shows the erector building up the iron lining in one of the Pennsylvania tunnels at New York. It shows clearly how the iron plates are bolted together to make the rings of iron lining.]

[Illustration: The last, or closing, plate of each iron ring is called the “key,” and is much shorter than the others. This photograph shows the shield erector on one of the Pennsylvania tunnels picking up and putting into place a key plate. This picture gives an idea of the mud and dirt and wet in which the men who work in tunnels have to do their work.]

[Illustration: Wherever possible, every space and crevice outside the iron lining is filled with cement forced, in a liquid state, through the iron lining by compressed air. This photograph shows the operation of “grouting,” as it is called. The man at the left is in control of the grouting. He has the hose, through which the grout is forced, screwed to a pipe which passes through a hole made for the purpose in the iron lining plates and called a “grout hole.” The two men in the middle of the picture are attending to the “grouting machine” by which the work is done. Water and cement are fed into the small boiler-like tank, the tank closed and compressed air admitted thus blowing the liquid cement through the hose and behind the iron lining. When no more grout can be forced behind the iron lining all the space has been filled. The man on the right is the engineers’ inspector taking note of how much grouting is done, and seeing that the work is properly carried out.]

[Illustration: This shows the process by which the iron lining is made perfectly water-tight, so that, when the compressed air is taken off, no water at all can get into the tunnel. Two operations are shown here. One is called “grommetting the bolts,” the other is called “caulking the joints.” The two men on the left, hanging on to the wrench, are tightening up the bolts as tight as they can after having put on, underneath the washers at the head and nut of each bolt, a ring of spun yarn dipped in red lead and oil or tar or some such water-proof material. A few of these “grommets” may be seen at the feet of the third man from the left. The other four men are caulking the joints between the iron plates by driving into the joints a mixture of sal ammoniac and iron borings. This sets as hard as iron and if properly done makes a perfectly water-tight joint.]

[Illustration: THE REMARKABLE ACCURACY OF ENGINEERING

Usually when crossing, with a tunnel, a wide river or estuary the tunnel is started from each shore and the shields are pushed through the ground until they meet somewhere about the middle of the river. This shows two of the Pennsylvania tunnel shields which have met far below the Hudson River. The white arrow shows where each shield ends. The platform of one shield on which the man stands corresponds exactly with the platform of the other shield. As may be imagined, it takes very careful and skillful engineering and surveying work, both before the work is begun and while it is being carried out, to enable tunnel shields to meet like this. This part of the art of tunnelling would take an article to itself.]

When the shield has been pushed across the entire length of the water way which has to be tunnelled, and the whole of the iron tube or shell is in place, a thick lining of concrete is placed inside the iron shell to protect it and make the tunnel stronger. As an added safeguard wherever the tunnel is in rock, gravel, strong clay or other ground which is not so soft that it does not close tightly in on the outside of the tube, liquid cement is forced by compressed air through holes made in the iron plates for this purpose. This liquid cement enters every pore or crevice in the surrounding ground and when it has set hard it still further protects the iron with a coating of cement. Pieces have been cut out of the iron lining of a tunnel built under the river Thames at London, England, in 1869, which showed that the iron at all places was as good as the day it was first put in forty years before, and iron put in the lining of the Hudson River Tunnel about 1878 when removed after thirty years was in perfect condition.

[Illustration: SHIELD AT END OF JOURNEY

Sometimes, however, shields are not driven to meet one another, but end their journey at some shaft or in some other tunnel previously built, after having gone through thousands of feet of all kinds of ground, from the hardest rock, which had to be blasted out foot by foot before the shield could advance, through hard pan, gravel, boulders, piles, rip-rap, made ground and mud so soft

that it flows like melted butter. Naturally, after an experience like this a shield does not look as spick and span as when it started in life. This photograph shows one of the shields of the Hudson and Manhattan Railroad in New York just reaching the end of its journey, battered and bent but still in the ring.]

[Illustration: This shows a piece of curved tunnel near Morton Street, on the Hudson and Manhattan Railroad, and is given because of the clear showing it gives of the iron lining. The track and floor are only the temporary roads for use during construction.]

[Illustration: Sometimes it is necessary to make borings of the ground below the tunnels. In some of these bore holes vast quantities of water are found at a much higher pressure than the tunnel compressed air. This picture shows a spouting bore hole in one of the Pennsylvania tunnels during construction.]

[Illustration: The last thing to do before laying the track is to put the concrete inside the iron lining. This picture shows this work going on and the wooden forms or ribs for holding up the concrete while it is setting.]

[Illustration: THE LAND END OF A GREAT TUNNEL UNDER THE HUDSON

This view is given to show how complicated an underground structure may have to be made to take care of the requirements of traffic. This view shows the three great reinforced concrete caissons sunk through the earth at Jersey City in order to contain the switches and crossings required to form the New Jersey connections of the uptown and downtown tunnels of the Hudson and Manhattan Railroad.

These caissons were sunk under air pressure by excavating below them just as though they were tunnels turned up on end. In sinking these caissons the material passed through was water-logged made ground, and the hulls of two sunken canal boats were encountered and had to be cut into pieces small enough to be taken out through the locks.

The usual passenger rushing at high speed in the trains between Jersey City and Newark and New York has little idea of the very complicated structure necessary to allow of his doing so.

The information in this article was supplied by Jacobs & Davies, Inc., Consulting Engineers, 30 Church Street, New York, the Engineers for the Pennsylvania Railroad, Hudson River Tunnels, the Hudson and Manhattan Railroad, and many other tunnels in various parts of the world.

The illustrations were kindly supplied by the Pennsylvania Railroad and the Hudson and Manhattan Railroad.]

~DANGERS OF TUNNEL BUILDING~

This account of tunnelling by shield and compressed air is very short and gives no more than a bare statement of the principles and chief methods of such work. Nothing has been said of the engineering difficulties involved in the design of such work, nor of the delicate surveying work necessary if one should hope to start two shields a mile or two apart and have them meet as shown in Fig. 13 like two great glass tumblers placed rim to rim after having travelled through thousands of feet of every kind of ground. Nothing has been said of the men who work on this most arduous form of subterranean navigation, how they cheerfully face the dark and the water ever threatening above them and the unseen but not less deadly ally, and yet foe, the compressed air, with its dreaded result, the bends, or the men on the surface who keep the air compressors running without pause or stop day in and day out until the work is done so that their comrades below may work in safety. Nothing has been said of the curious accidents that are liable to occur as when the air pressure in the tunnel gets too high, overbalances the water pressure and blows a hole through the river-bed and forms a geyser in the river above. It gives no account of the special difficulties which arise when special conditions are found; for example, when the lower part of the tunnel is in rock and the upper part is in soft material. In fact it is nothing more than a bare outline but it hoped that some, who may not be clear in their minds as to how tunnels are built, may learn some of the first principles of this most romantic kind of work from this bald narrative.

Why Do My Teeth Chatter?

Your teeth chatter because when you are cold in a way that makes your teeth chatter the little muscles which close the jaw act in a series of quick little contractions which pull the jaw up, and then let it fall by its own weight. This is repeated many times and, as the action is quick, the chattering occurs. It is a peculiar thing that this occurs in spite of the will or brain, when, as a matter of fact, these muscles which operate the jaws are especially under the control of the brain. The chattering is really a spasm caused by the cold, and all spasms act independent of the will. Cold seems to act on the jaw muscles a good deal like some poisons which cause

spasms.

Where Did All the Water in the Oceans Come From?

No, it did not come from the rivers which empty themselves into the oceans, because the oceans were there before the rivers existed. Part of it comes from the rivers now, but only a little in comparison to all the water there is in the ocean. I will try to tell you simply how all the water got into the ocean.

There was a time when there was no water on the earth at all. That was when the earth was red hot, just as it is to-day on the inside, and at that time all the water we have to-day was up in the air in the form of gases. Strange as it may seem to you, if you take two gases, one called hydrogen and the other oxygen, and mix them the right way, they will turn into water, and if you had the right kind of chemical apparatus you could take water and turn it into these gases again. When, then, the earth was still all red hot, all of our water was up in the air in the form of these two gases. Then, later on, when the amount of heat on the earth was just right to make these gases mix together, the water came down out of the air in great quantities, and there was so much of it that it completely covered the whole earth and no land was visible. Later on, for various reasons, mountains were thrown up on the earth's surface by great earthquakes, and every time a mountain or a high place was formed there had to be a hole or low place some place else, and the water ran into these low places and stayed there, and that uncovered more of the land, because there wasn't enough water to fill all the holes and cover the land too, and that is what makes our continents and islands and all of the land we see. There is now about three times as much earth covered with water as there is land. Of course, the sun is always picking up water through what is called evaporation, which means that it is taken into the air in the form of gases. Later it comes down again in the form of rain and falls into the oceans or on the land, where it sinks in, finally finding a stream or river, and sooner or later gets back into the ocean again.

Why Don't the Water in the Ocean Sink In?

This is due to the fact that there is a kind of substance at the bottom of the ocean which the water cannot penetrate, in spite of the tremendous pressure which the great body of deep water exerts. In all places where the bottom of the ocean has a covering which water can sink into it does so, but there are such a few places where this is possible, by comparison, that the amount that gets out that way is not noticeable. This water, if it can keep on going, will eventually reach the inside of the earth, where it is red hot, and is turned into steam.

Where Does the Water in the Ocean Go at Low Tide?

To get to the answer of this you must know something about the tides. The tide is caused by the pull of the moon on the waters in the ocean. The moon revolves about the earth once each day and has the ability to draw up the waters in the ocean toward it, as we have seen in our study of the tides.

Now, when it is high tide in one place it is low tide in another. The moon does not make more water, but only pulls it toward it from side to side. When it is low tide where we are the water has simply moved as a body toward the place where it is high tide.

The tides act a good deal like a see-saw, except that they move from side to side instead of up and down. When one end of the see-saw goes up the other end goes down, and when the "down" end comes up the other end goes down. So the answer to your question really is that at low tide the water which made it high tide a few hours before has gone to some place where it is at that moment high tide.

Why Does the Ocean Look Blue at Times and at Other Times Green?

Sometimes when we look at the ocean from the pavilion or while on the sand of our favorite bathing beach the water in the ocean looks very beautifully blue, and on other days will look dark green from the same point. Why is it? If you will stop to think that at night when there is no moon or other light the water in the ocean looks black, I think you will soon be on the right track to answer the question yourself.

When the sky is blue--the kind of blue we like to see in the sky when we are at the beach--the water in the ocean is blue, because the sea reflects the color of the sky, and when the sky is overcast and gray the color reflected by the sea will be gray also.

But, say you, sometimes the water in the ocean is dark green, and yet the sky is never green. Quite true, and I will try to tell you what produces the green color. This happens sometimes where the water is shallow, either near the shore or out further where there is a sandbar or other shallow place. Sometimes at such points the sunlight strikes the water at such an angle that the rays go clear to the bottom and are reflected from that point--the bottom--to our eyes. In such a case the light will be changed through a combination of the color of the bottom at that point and the color of the sky itself at the time to make the color green as it is reflected to our eyes from the bottom.

Why Does Water Run?

Water runs because it has not enough of anything in it to make it stick together.

In school language we call this sticking-together-thing “cohesion.” The principle of cohesion makes all the difference there is, so to speak, between solids, liquids and gases. A brick, a stone, a stick of wood, or a piece of iron and all other solid substances have a certain amount of this property of cohesion, and the particles stick together, enabling us to build buildings and other things which become permanent structures. These solid substances are either naturally cohesive or else man, as in the case of the brick, has brought together certain things with little or no cohesion and made them stick together permanently. In the case of the brick, he takes a quantity of clay, which is cohesive only to a certain degree, bakes it in an oven and it becomes hard enough--more cohesive--so that he can pile one on top of the other and make a building. Then he puts sand, mixed with other things--lime and water--between the bricks to hold the bricks together, and makes a structure that will last. Two bricks have no natural cohesion for each other and, therefore, they can only be held together by something that has cohesion within itself and also for the bricks. The lime, sand and water make mortar which is cohesive when properly mixed, while in themselves neither lime nor sand have much cohesive property, and water has none at all.

Liquids have little or no cohesion. Water has none, or very little. Syrup has a good deal more, but will run over the edge of a piece of bread and butter if you are not careful.

Gases have no cohesive properties at all and, therefore, fly all over the place, through any opening they can find, either at the top of the room or under the crack of the door. They are always trying to get to some place else and will keep moving as long as not confined. Gases can move in any direction.

Liquids, however, while they are inclined to be constantly on the move, can only go in one direction--down hill, and they go down fast or slow if there is a chance, in proportion to the amount of stick-together properties they have. Liquids can never go up of their own accord, excepting in the process of evaporation, and then only when changed into gases. A lake of water will dry up completely by evaporation unless fed by streams of water constantly flowing in, because evaporation is constantly taking place wherever water is exposed to the air.

What Makes the Water Boil?

What we call boiling in the water we see when water is put over a hot fire long enough to make it boil, is the changing of the water from what we generally regard it--a liquid--into gases. Water consists of two gases--hydrogen and oxygen--in fact, two parts of hydrogen gas and one part of oxygen gas when mixed will always make pure water. Now, then, if liquid water is heated to a certain point or temperature it turns into the two gases, oxygen and hydrogen, and comes to the top of the water, which still remains in liquid form, in the form of a bubble and explodes into the air--not a very loud explosion, but still an explosion. The process of turning liquid water into gases is a gradual one, and that is why the water does not all turn into one large bubble at once and explode away. If you keep the fire going long enough, all the water in the vessel will explode away into the air, a few bubbles at a time. If you hold a cold plate over the vessel as the bubble explodes you can catch some of these gases in the form of bubbles on the under side of the plate, which are again liquid water. When the water becomes hot enough it turns into bubbles and as bubbles rise that is what makes the boiling you see. When the same gases then come together again in a certain proportion under proper temperature they turn into liquid water.

At What Point of Heat Does Water Boil?

The boiling point of water is the temperature at which it begins to pass into the form of gases. This varies in different altitudes. At the sea level the boiling point is at 212° Fahrenheit. On the top of mountains, for instance, water would boil at a much lower

temperature. It would be possible to go high enough in a balloon so that the water would fly from the pan in the form of gas without making the water hot. Also, a mile below the level of the sea it would take many more degrees of heat to make the water boil. It is said that high up in a balloon you could not boil an egg hard in a pan of boiling water if you kept it in the boiling water for an hour or more, whereas we know that an egg will be hard-boiled if we keep it in boiling water down where we live for more than five minutes.

The degree of heat at which water passes away into the form of gases is regulated by the pressure of the air on the water and other things about us. At the average level in the United States where people live the pressure of the air on everything is fifteen pounds to the square inch, and at this pressure water boils only after it reaches a temperature of 212° Fahrenheit. As we go up the mountains the pressure becomes less and less as we go up. At the top of Mount Blanc, which is 15,781 feet high, water boils at 185° Fahrenheit. If we took a balloon from the top of the mountain we would come to a height where there was no air pressure at all.

What Do We Mean by Fahrenheit?

The name Fahrenheit is used to distinguish the kind of scale most commonly used on thermometers in Great Britain and the United States. Gabriel Daniel Fahrenheit, a native of Dantzic, made the first thermometer on which this scale was used, and it is named after him. In this scale for thermometers the space between the freezing point and the boiling point is divided into 180 degrees--the point for freezing being marked 32 degrees and the boiling point 212 degrees.

Why Can’t We Swim as Easily in Fresh Water as in Salt Water?

Our bodies are heavier than fresh water, i. e., a bulk of fresh water equal to the size of our body would weigh less than our body, so that the first tendency is to sink to the bottom if we find ourselves in fresh water. If man had not learned to swim that is what he would always do, sink to the bottom; but having learned how to keep from sinking, he is able to swim in fresh water. However, we find that an amount of salt water equal to the bulk of a man in size is heavier than an equal amount of fresh water, although such a bulk of ordinary salt sea water will still weigh less than the man. A man will sink in salt water also if he has not learned to swim or float, but he can keep up with less effort in salt water, and also swim in it more easily. In a nutshell, then, the answer to this question is that salt water is heavier than fresh water. You can make salt water so full of salt that it becomes heavier than a man. Great Salt Lake in Utah is so salty that one cannot sink in it for this reason. You could drown yourself in it, of course, by keeping your head under water, but whether in shallow water or deep water you would not sink in Great Salt Lake.

Why Do We Say Some Water Is Hard and Other Water Soft?

What we call hard water contains certain salts which soft water does not contain. This salt in hard water is lime or some other salts which the water has picked up out of the ground as it passed through either coming up or going down. On the other hand, we can guess after having been told this much that if we can find any water that has not passed through the ground, and, therefore, not had a chance to pick up any salts, we will have soft water. From that point it is easy to guess, then, that rain water must be soft water, and so it is. The water in the cisterns, which is rain water, is soft water, and the kind we get out of the wells is hard water.

We do not like to wash either our faces or our clothes in hard water, especially when it is necessary to use soap, because when we use soap with hard water the soap undergoes chemical change which prevents its dissolving in the water. Therefore, you cannot easily do a good job of washing in hard water. On the other hand it is easy to dissolve the soap in pure rain water or soft water and that is the kind we, therefore, prefer for washing.

How Does Water Put a Fire Out?

This is at first a puzzling question, because back in your mind is the thought that since hydrogen and oxygen are necessary to make a fire burn, it seems strange that water, which is composed of oxygen and hydrogen, will also put it out.

A burning fire throws off heat, but if too much of the heat is taken from the fire suddenly the temperature of the fire is sent down so far below the point at which the oxygen of the air will combine with it that the fire cannot burn. We speak commonly as though water thrown on a fire drowns it. That is practically what happens. Scientifically what happens is that the water thrown upon the fire absorbs so much of the heat to itself that the temperature of the fire is reduced below the point where oxygen will combine with the carbon in the burning material and the fire goes out.

To answer the unasked part of your question at the same time I will say that hydrogen and oxygen when combined as water will put the fire out rather than make it burn, more because when these gases take the form of water they are already once burned, and you know that anything, substance or gas, which has already been burned cannot be burned again. It required great heat to make oxygen and hydrogen combine and form water, and it also takes great heat to separate them again. So they are really burned once before they become water.

Where Does the Rain Go?

Eventually almost all of the rain that falls runs into the rivers and lakes and later finds its way into the ocean, where it is again taken up into the air by the sun's rays. But many other things happen to parts of the rain which do not find their way into the ocean. In the paved street, of course, where the water cannot sink in, it flows into the gutter and thence into the sewer and on down to the river or wherever it is that the sewers are emptied. You see, it depends very much on what the earth's surface is covered with at the place where the rain falls. When it strikes where there is vegetation a great deal of it stays in the soil at a depth of comparatively few feet. If it is soil where trees and other plants grow a great deal of it is sucked up from the ground by this vegetation and given back into the air through the leaves and flowers. Some of the rain keeps sinking on down into the earth until it strikes some substance like rock or clay, through which it cannot sink, and then it follows along this until it finds something it can get through and collects in a pool and forms an underground lake, and may cause a spring to flow. Then there are also worms and other forms of animal life in the earth which use up some of the water. But it all gets back into the air eventually to come down some time again in the form of rain.

Why Does Rain Make the Air Fresh?

The main answer to this question must be that the rain in coming down through the air drives the dust and other impurities which are in the air before it, and so cleans the air and makes it absolutely clean. In addition to this it is now stated that since very often rain is produced by electrical changes in the air, and that these electrical changes produce a gas called ozone, which has a delightfully fresh smell, it is this ozone that makes us say the air has become fresh.

The air above our cities is almost constantly filled with smoke, containing various poisonous gases, and these are driven away by the falling rain.

Then, too, there is always a greater or less accumulation of dirt, garbage and other things in the cities which give off offensive smells constantly, but which we do not notice always because we become used to them. When the rain comes down it washes the streets and destroys these smells, and that makes the air fresh and delightful to take into the lungs.

In the country the air is more nearly pure all the time, because the things which spoil the air in the city are not present.

Is a Train Harder to Stop Than to Start?

The answer is yes. It is harder to stop a train than to start it, or rather it takes more power. The speed of a train depends upon the motive power. When a train is stopped and you wish to start it, you must apply enough motive power to start it going. There must be enough power to move the weight of the train and overcome the friction of the wheels on the track. It is, of course, easier to move a thing that weighs less than a heavier one. If you throw a ball ten feet into the air, it will perhaps not sting your hand when you catch it on its return; but, if you throw it one hundred feet into the air, it will sting your hands when you catch it. Besides, it will come down faster the last ten feet of the way than the ball which you threw only ten feet into the air. This is because when movement is applied to anything you add power to it. The ball which comes down from one hundred feet in the air acquires more power in falling and it takes more power to stop it. A train in motion has not only the power of the weight of the train behind it, but also the additional weight which the movement of the train has given it. Therefore, it takes more power to stop it than to start it. To stop a train you must apply the same amount of power as is in the moving train because the power to stop any moving thing must always be at least as great as the power which is moving it.

What Makes the Knots In Boards?

We find knots in the boards which we notice in a lumber pile or in any other place where boards happen to be, because the smaller limbs which grow away from the larger limbs of trees grow from the inside as well as the outside of the tree.

When you see a knot in a board it means that before the tree was cut down and the log sawed up into boards, a limb was growing out from the inside of the tree at the spot where the knot occurs.

You will also find that the wood in the knot is harder generally than the rest of the board. This is because more strength is required at the base of a limb and in the part of the limb which grew inside the tree than in other parts, for the limb must be strong enough to support not only the limb itself, but also the smaller limbs which grow out of it.

How Many Stars Are There?

Man may never know how many stars there are. The best we can do is to figure on the number that can be seen with the largest telescopes which have been invented, for, of course, you know there must be many millions of them which to us are invisible. We have counted the stars so far as we can see them; or, rather, so far as we can photograph them. Astronomers have found that a photographic plate exposed to the stars will show more of them than can be seen by the naked eye. This is because the materials on a photographic plate are more sensitive to the light of the stars than the human eye. By this method man has been able in a way to count the stars he can see. It adds up to more than a hundred million of them. Astronomers found this out by taking photographs of the heavens at night, devoting one picture to each section, until the entire heavens had been covered, and then counting them.

[Illustration: WHERE PAINT COMES FROM

MAKING LEAD BUCKLES--THE FIRST STEP IN PAINT MAKING.]

The Story in a Can of Paint

Paint such as is most frequently used is the material used for painting buildings, such as houses, barns, stores, and many others which we need not mention here. This paint is used on these buildings mostly for two very important reasons--one being to beautify the buildings, the other being to protect them from the ravages of the weather, much in the same way that your clothes protect you from the weather.

Paint such as we mention here may be regarded as the most simple and useful form. You have no doubt frequently seen the painter-man spreading paint on some building, or perchance, you have seen your father doing it, and have noticed that paint is a fluid substance looking something like cream, which is applied to the surface to be painted with a suitable brush and is brushed out smoothly. After the first coat is dry, other coats are put on in the same way until enough paint has been put on to thoroughly hide the unevenness of the lumber and making it of a uniform color.

This paint is made by simply mixing together dry powder, which is usually called pigment, with a thin, yellowish liquid which is called linseed oil. In the earlier days, the painter-man mixed this paint himself whenever he desired to use it. In these more modern times, he usually buys this paint already prepared.

Perhaps a little history of the preparation of the package of a can of paint which he buys may be interesting to you.

Let us imagine that the can of paint is white. In this case, the pigment which is used is a white powder and is made of either metallic lead or metallic zinc. The preparation of this fine white powder is very interesting and requires considerable time to perfect.

Let us consider the pigment known as white lead first. This is produced by causing metallic lead, which is of a bluish-gray color and very heavy, to change from its original form by a process which is known as “corrosion.” This corrosion is brought about by first taking the metallic lead, which at this stage exists in large pieces known as “pigs.” These pigs of lead are melted in a furnace and then molded into small, thin shapes which are buckles.

[Illustration: HOW WHITE LEAD IS MADE

FILLING THE STACK WITH LEAD BUCKLES.]

[Illustration: LEAD BEING TAKEN OUT OF THE STACKS.

The next step is to take an earthenware vessel, which resembles an ordinary stone crock, and first pour into it a small quantity of acetic acid, which is about the same as table vinegar. Then the crock or pot is filled up with the lead buckles.

Where this white lead is made in a large way many thousands of these pots are placed in a building, the sides of which are walled up tight, the spaces between the crocks being filled in with tan bark. After the floor has been covered with a layer of these crocks, the layer is covered with boards, in order to provide a foundation for setting in the next layer of crocks and tan bark. The layer of boards also serves as a floor to keep the tan bark from falling into the open crocks on the tier below. This procedure is followed with tier after tier until the building is completely filled.

Corrosion of the metallic lead in the pots now begins, because the tan bark generates some heat, becoming finally quite warm. This heat causes the acetic acid or vinegar to throw off vapor or steam, which attacks the metallic lead, causing it to decompose or corrode. This process goes on for many weeks (sometimes as much as fifteen or sixteen weeks), until those buckles of metallic lead have become a mass of white powder and nearly all trace of the original metallic lead has disappeared.]

[Illustration: A LEAD BUCKLE AFTER CORROSION.]

[Illustration: A LEAD BUCKLE BEFORE CORROSION.]

[Illustration: HOW OXIDE OF ZINC IS OBTAINED

WASHING THE LEAD. SCREENS COVERED WITH CLOTH REMOVE ALL FOREIGN MATTER.

After these many weeks have passed, the pots containing the white powder of carbonate of lead, as it is called, is taken out of the building where corrosion took place, and the white deposit is put through an elaborate system of refining, which is called “washing,” and, in fact, is really washed in water, and is then dried in very large copper pans. After being dried it is in the form of large white cakes, resembling pieces of chalk. These cakes are then passed through a mill, which grinds them to very fine powder, which is packed in barrels ready to be shipped and used by the paint-maker.]

[Illustration: FURNACE WHERE THE SULPHUR IS ROASTED OUT OF THE ORE.

Now that we have followed through the process of making the white-lead powder, or pigment, let us take a little time to study the preparation of the other white powder, known to the paint trade as “oxide of zinc.” This is prepared in a manner quite different from that of the white lead.

First the ore which is mined from the earth containing the metallic zinc is carefully selected by expert workmen and placed in a special kind of furnace, being mixed with hard coal, such as we use in our heating stoves.]

[Illustration: A ZINC SMELTER--THE MEN KEEP THEIR MOUTHS COVERED SO AS NOT TO INHALE THE VAPOR, WHICH IS POISONOUS

The burning of the coal causes an intensely high temperature, sometimes being several thousand degrees. This causes the zinc ore to be consumed as it were or to pass into a form of vapor. This vapor is carried through huge pipes which are several feet in diameter and extend for a long distance. While these vapors are passing through these pipes it becomes cooled. After becoming cooled it takes on the form of very fine white powder, coming from the pipes in much the same way that snow falls from the sky in the winter. This is collected and placed in barrels, after which it is ready for the paint-maker without further preparation.]

~WHERE LINSEED OIL COMES FROM~

Since we have followed the preparation of the two important white pigments used in making our can of paint, it is now important that we devote a little thought to the liquid which is to be used. This is called “Linseed Oil.” Linseed oil is of a golden yellow color, resembling the appearance of thin syrup which we sometimes have on the table. This oil is taken from the seed of the flax plant. It might better be called “Flaxseed Oil,” yet it is not commonly known by that name, but is nearly always referred to as “Linseed Oil.” Flax is grown in many parts of the world, the most important places being the United States of America, Dominion of Canada, Ireland, India and the Argentine Republic. In the United States, the seed is sown early in spring, much the same as is done with other crops, and ripens and is harvested early in the fall of the year. The harvesting and separation of the seed from the plant or straw is done very much in the same way that other crops, such as wheat and oats, are harvested. The seed is then taken to market and is ready for the extraction of the oil, which is done by men who are known as “oil crushers.”

[Illustration: PRESSING OIL OUT OF FLAXSEED.]

[Illustration: REMOVING OIL CAKE FROM PRESS.]

The oil is extracted from the seed by a very simple process. Usually the seeds are heated by steaming them, after which they pass through a mill, being ground to a coarse mass, which is then placed in very powerful machines called “Hydraulic Oil Presses,” which squeeze the oil from the seed, leaving the remainder in the form of large cakes which are then ground to a mealy-like powder which is used as food for cattle and is very much prized.

The oil which has been extracted by this process is put into large tanks where it is clarified and is then ready for the paint-maker. This oil is often referred to as “Vegetable Oil” and it has one very peculiar and very important characteristic which makes it useful and necessary for use in paint. This property is that of drying or becoming solid, losing all tendency to stickiness after it has been spread out thinly and exposed to the air for a short time.

[Illustration: WHERE LEAD IS GROUND IN OIL.]

[Illustration: WHERE PAINTS ARE MIXED.]

Now that we have given attention to the preparation of the most important things used in the making of our can of paint, let us look a little to the manner in which they are put together, and the result.

The oil is necessary in making paint in order to make it fluid, so that the paint may be brushed on to the wood or other surface, and also so that the pigment or powdered material which has been put into the paint will have something to hold it to the surface. The oil or other liquid which may be used is usually called “Binder” by the paint man because it binds the pigment in the paint and to the surface on which it has been spread or applied.

In a large paint factory, the two white pigments, lead and zinc, are mixed with linseed oil in large machines known as “Mixers” into a smooth paste which is then run through other machines called “Mills,” where the paste is ground very fine into large tubes where the paint is finished by mixing in enough more oil to make it of the proper thickness or consistency for brushing. In this state it can be used, but would not be entirely satisfactory because it would dry very slowly. For that reason, the paint-maker adds in a small amount of what is known as “Drier,” which causes the paint to dry much more rapidly after it is spread out on any surface.

The paint-maker may also add in a small amount of thin liquid called “Turpentine,” which also aids in the drying and the working of the paint. Turpentine is a very thin liquid which looks like water, and it is derived from the sap of one species of pine which grows abundantly in the southern portion of the United States. The sap is taken from the tree by tapping the tree or making an incision called a box, at certain seasons. After the sap is collected it is put through a heating process called “distilling,” which separates the water-white liquid, called turpentine, leaving a large mass of heavy material which is commonly known as “Rosin.” This turpentine is very useful to the paint-maker and the painter. It is also used for many other purposes.

~WHAT MAKES THE DIFFERENT COLORS OF PAINT~

The paint which we have described is the most simple kind and is white. There are many other kinds of paint used, being of many different colors. All of these different kinds require different treatment and preparation and would require many large books to explain even in a brief way.

The white paint which we have described may be colored or tinted to many different hues by adding suitable color pigments. These color pigments are of many kinds and are derived from many different sources. The vegetable kingdom is represented as well as the mineral and animal kingdoms. The linseed oil which we have already mentioned, is derived from the vegetable kingdom. This also applies to some few of the pigments. A very important instance which we might mention is a beautiful rich brown called “Vandyke Brown.” This is made from decayed vegetation which is found in swampy districts. There are many pigments derived from the mineral kingdom. White lead and zinc oxide have already been described as useful. Among colored pigments coming from this kingdom, we might mention yellow ochre, sienna, umber, cobalt blue, and many others.

The animal kingdom supplies quite a number, one of which is a beautiful red known as “Carmine.” This is taken from a small insect or fly which is found in certain tropical climates. The production of carmine is very expensive and the product is highly prized.

Another important development of the animal world is what is called “Bone Black.” This is made by taking ordinary animal bones, putting them into a suitable furnace and burning them, which really produces bone charcoal, which is refined by powdering and washing, and finally produces a beautiful black, such as used for painting fine coaches and carriages.

Why Does a Dog Turn Round and Round Before He Lies Down?

Away back in the history of the animal kingdom, when the ancestors of our domestic dog were wild, they slept in the woods or open. When they were ready to lie down, they first had to trample the grass about them flat to make a place to lie down. This became a habit and one of the instincts of the animal which has been transmitted to the dogs of today who keep it up. It is an inherited habit quite useless to the dogs of to-day.

How Is Light Produced?

You already learned that a substance called ether is found in all substances, filling the spaces between the molecules. When the molecules are made to vibrate, the ether naturally also vibrates. As soon as the vibrations become sufficiently rapid, they produce the sensation of light. These vibrations also produce heat. In heated bodies the molecules are always found to be in vibration, and a body may become so hot that it gives off light. We notice this when iron becomes red hot. Heat and light are found together in bodies in many instances. In fact, most of the light we have comes from bodies which are hot. The sun is so hot, that it is surrounded by the gases of many substances that exist as solids on earth.

We have some bodies which produce light which is not accompanied by much heat. The glow-worm, or firefly, seems to make light with little or no heat; but we do not yet know how this is done. Almost all sources of artificial light require that heat be produced before light obtained. Only such vibrations of the ether which are sufficiently rapid produce enough light to enable us to see. For this reason, a piece of red hot iron, which is made luminous by heat and whose particles vibrate less rapidly produce little light.

What Makes Rays of Light?

Whenever the ether is made to vibrate rapidly enough at any point, the vibrations go in straight lines from the source of light in all directions. A single line of vibrating particles in the ether, is known as a ray. A number of rays, that issue from one point, are said to form a pencil. A pencil of light may be produced by holding near a candle a screen, with a hole in it. Sometimes rays of light are brought together in a point, as may be done by means of a burning glass, and one of these bundles of rays is known as a convergent pencil.

A bundle of rays that lie parallel to each other forms a beam. The rays that come to us from the sun are practically parallel and are called sunbeams.

Why Does a Nail Get Hot When I Hammer It?

When we are in the sunshine, or standing before a fire, we feel hot; when we take snow or ice in our hands, they feel cold. The thing which produces these sensations is called heat. When we feel heat, it is because heat is absorbed by our bodies, and when we feel cold, it is being thrown off by them.

To answer this question, we must see how heat may be produced. If we draw a cord rapidly through our fingers, they feel hot, and if we rub a coin briskly with a cloth or our hands, it becomes warm; if we take a nail and hammer it on a hard substance, it becomes too warm for us to hold. In these instances heat is produced by retarding or checking the motion of a body. When we draw a cord through our fingers, it moves less easily; we retard its motion by gripping it and this is what makes the heat we feel. When we strike the nail with a hammer, the motion of the hammer is checked by the nail, and the faster we pound with the hammer, the hotter the nail becomes. From these experiments we learn that whenever the motion of a substance is checked, or retarded, heat is generated, and the substance made hot.

In explaining this method of producing heat, it was at one time thought that all bodies contained a substance which produced the heat and that, when rubbed or hammered, this substance was thrown off. About the end of the 18th century, however, it was shown by Benjamin Thompson (Count Rumford), that substances when rubbed give off heat. From this we learned that heat is not a substance, because the quantity of any substance, present in a body, cannot be limitless. If it were a substance which produced the heat, the supply would sooner or later be exhausted, and rubbing could no longer produce heat.

Heat produced by rubbing, or by striking substances together, is caused as follows: If two substances are struck upon each other, the whole of those substances are checked, but the molecules of the substances are made to vibrate very rapidly, and these vibrations produce the heat we feel.

How Do We Obtain Heat?

We get most of our heat from the sun. If the heat from the sun did not reach us, no living thing would exist on the earth. No plants or animals could live; the oceans and rivers would be solid ice.

Another important source of heat, is chemical action. Chemical action is what causes fire. Even when it does not cause fire, it produces a great deal of heat. When we breathe to keep our bodies warm, it is a chemical action that occurs. Fire is the most important form of chemical action, as a source of heat.

Why Does a Glow-Worm Glow?

A glow-worm is a kind of beetle which may be found in the yards and hedges in the summer time. The name applies only to the female of the species which is wingless and whose body resembles that of a caterpillar somewhat and emits a shining green light from the end of the abdomen. The male of this species has wings but does not show any light as does the female and resembles an ordinary beetle. The male flies about in the evenings looking for the female and she makes her light glow in order that the male may find her. Glow-worms are found mostly in England. There are, however, some members of the same species of beetle common to the United States. We speak of them as fireflies or lightning bugs. The female of these also is the only one carrying a light, although unlike the glow-worm she has wings and can fly.

Why Do They Call It Pin Money?

This expression originally came from the allowance which a husband gave his wife to purchase pins. At one time pins were dreadfully expensive so that only wealthy people could afford them and they were saved so carefully that in those days you could not have looked along the pavement and found a pin which you happened to be in need of as you can and often do today.

By a curious law the manufacturers of pins were only allowed to sell them on January 1st and 2nd each year and so when those days came around the women whose husbands could afford it, secured pin money from them and went out and got their pins.

Pins have become so very cheap in these days that we are rather careless with them, but the expression has continued to live although today when used, it means any allowance of money which a husband gives a wife for her personal expenses.

Pins were known and used as long ago as 1347 A. D. They were introduced into England in 1540. In 1824 an American named Might invented a machine for making pins which enabled them to be manufactured cheaply. About 1,500 tons of iron and brass are made into pins every year in the United States.

Why Do People Shake Hands With the Right Hand?

In the days of very long ago when all men were prepared to fight at any and all times because one could not know whether another approaching was a friend or an enemy, all men went armed. This was before the day of guns when the sword was the great weapon of defense.

Upon occasion when one man approached another, each had to decide whether the other came on a peaceful mission or not.

People in those days were mostly right handed as they are now and when fighting carried their swords in their right hands.

If, then, a man wished to speak with a stranger or, as might easily be necessary, to one who may even be known to be unfriendly, he put out his right hand upon approaching to show that he had no deadly or dangerous weapon in it. The other man could see this and knew from the extended open hand that no harm was intended and that the approach was peaceful. If, then, he was willing to meet the other, he also extended his right arm with the hand open to show him who was approaching that his fighting hand was empty also; and when they met each would grasp the hand of the other so that neither one could change his mind and assume a fighting attitude without the other having an equal warning.

How Did the Custom of Clinking Glasses When Drinking Originate?

In the days of the Roman gladiators, before a duel with swords, it became the custom of each of the participants to drink a glass of wine before fighting. Just before the fighting commenced two glasses of wine were brought and the gladiators drank. These two

glasses of wine were provided by the friends of either one or the other of the gladiators. To guard against treachery, through some over zealous friend of the fighters furnishing poisoned wine was necessary. So before drinking and to show there was no treachery, the gladiators came close together and poured wine from one glass into the other back and forth until the wine in the glasses was thoroughly mixed. If the wine in one glass then had been poisoned, the poisoned wine would thus be in both glasses, and if there had been any treachery, both gladiators would be poisoned if they drank. The wine was poured from one glass to the other to show that there was no treachery.

This custom continued in use for a long time until the idea of drinking before a fight was abandoned. The custom, however, of showing friendliness in this way while drinking continued for a long time. Later it became a mere custom, however, to show a friendly spirit toward the one who was drinking with you, and when the danger of poisoned wine was past, the actual act of pouring the wine from one glass to another was changed to merely touching the glasses together. Thus today we have the friendly custom of touching glasses together long after the necessity of guarding against treachery while drinking has passed.

Why Cannot Fishes Live In the Air?

It is a curious thing isn't it that if a boy falls into the water, he will drown if he cannot swim or someone does not help him out, and that if a fish falls out of the water onto the land, he will drown also, even though he knows how to swim, better than anything else he does. A boy cannot secure the air which he needs to live on if he is under the water, because there is not enough air for him there and a fish cannot secure enough air for him to live on when he is on land where the air is plentiful, because, the boy takes his air from the air itself and the fish gets his air out of the water.

To live by breathing the air we find on or above the land, it is necessary to have lungs and fishes do not have lungs. In the case of the boy under the water he would have to have gills to enable him to make use of the air which is in the water to live by and he has no gills.

A fish can only live a little while out of the water, but even so he can live longer out of the water than a boy can under the water.

Lest you read sometime of the flying fish and think they must be able to live out of the water, I will tell you before you ask the question that the flying fish never stays out of the water for more than a few seconds at a time. His flying leaps amount to little more than long leaps from wave to wave. He swims along very fast in the water, coming right up to the surface and out into the air and the speed at which he has been swimming regulates the distance he will go when he shoots into the air, as he has no means of propelling himself through the air, but only into it. He has, however, wing-like fins, which he spreads out when in the air and which enables him to glide through the air and thus remain in the air longer.

What Makes a Fish Move in Swimming?

This is a puzzling question, I am sure. Of course, you at once cause several other questions as soon as you ask this one such as the following: Does the water in front of him move out of the way and then close in behind him? If so, where does it go in the meantime? Does the fish move the water forward or up or down or what does he do?

The answer is, of course, in the movements of the fish's tail. The fish in swimming is surrounded with water, top, bottom and all sides of him. The pressure of the water on the fish is the same at all points so that any motion made by him would have a tendency to make him move. As a matter of fact the tail in moving from side to side creates a current in the water from the head to the tail, or rather would produce an actual current if the fish remained perfectly still. Instead of making an actual current of water, the body of the fish is moved forward.

As to whether the water ahead of him opens up first and then the water behind him is a more difficult question to answer. To the appearance it would seem as if the water moved at both ends and sides at once, but according to scientific theory, the water at the head of the fish is displaced first.

Why Are Birds' Eggs of Different Colors?

This is a wise provision of nature to help the mother birds hide her eggs away from the eyes of her enemies. In the animal kingdom every kind of life is the natural prey of some other kind of animal. A bird will have enemies which try to catch her as food. A bird cannot fight back, so must fly away when danger threatens, in order to save her life. This means that she must leave the eggs in

the nest for the time being. At certain times she must also leave her nest and search for food for herself. In order that the eggs so left alone may have a better chance of not being discovered, nature has arranged matters so that the eggs take the color very much of the surroundings in which they are laid. Eggs of some birds are spotted or look like pebbles, because the mother bird lays them in the sand. Some of them are green, almost the color of the materials from which the bird builds the nest, and so the colors have a real, and to the birds, a valuable purpose.

Why Does a Hen Cackle After Laying an Egg?

The hen cackles because she is glad. She is glad because she has just accomplished something, which she was put on earth to do. If you study the life on the earth carefully with this in mind, you will discover that all kinds of life give expression in some form of gladness, when they have performed the things they are on earth for. It's the hen's way of expressing herself and letting the chicken world know. The dog wags his tail when he is pleased; boys and girls jump up and down when they are pleased, whether they have been doing anything commendable or not. No doubt also the actual laying of the egg causes some discomfort to the hen and the corresponding feeling of gladness would come naturally after the discomfort disappeared.

Why Will Water Run Off a Duck's Back?

The reason that water runs of a duck's back, is that the feathers of ducks are oily and, as water and oil will not mix, the water runs off instead of soaking in. The feathers on a duck are so thick on the body of the duck, top and bottom, that even if it were not for the oil which is on the feathers the water would have some difficulty in soaking through the feathers. But the main reason why the feathers on a duck's back cause water striking them to run off is that the duck has an oil gland which is constantly producing grease or oil and which the duck uses in giving his feathers a thin coating of oil to make them slick with oil and when any water strikes the duck it runs off. Other birds which live in the water a great deal have this oil gland for the same reason.

THE STORY IN A STEEL RAIL

[Illustration: A Blast Furnace.

Molten iron is brought from the blast furnaces to the open-hearth furnaces, and dumped into a receptacle called a mixer, the capacity of which ranges from 400 tons to 1000 tons, depending upon the number of furnaces to be served.]

[Illustration: One-thousand-ton Mixer.]

Pictures in this story by courtesy of Bethlehem Steel Co.

[Illustration: INSIDE OF OPEN HEARTH FURNACE

Charging Side of an Open-hearth Furnace.

An open-hearth furnace consists of a long, shallow hearth, suitably enclosed in fire-brick, and bound together with steel binding. The furnace is heated by burning gas and air, which have previously been preheated, so that a temperature is obtained in the furnace ranging from 2900 to 3050 degrees Fahrenheit.]

[Illustration: Pouring Side of an Open-Hearth Furnace.

The open-hearth process consists of the purification of iron by oxidizing out the impurities and burning out the carbon of the iron until a tough and ductile steel is produced, which can be made of any desired composition by the addition of the necessary quantities of alloys just previous to tapping and pouring. The impurities in the iron are oxidized by the slag lying on top of the metal, and the burning out of the carbon, which is a very slow operation, is hastened by the addition of iron ore, the oxygen of which combines with the carbon of the iron and passes off is a gas going up the stack.

When an open-hearth furnace is ready for a charge, a variable amount of scrap, say 30 per cent of the total weight of material used for the heat, is charged into the furnace. With this scrap is charged sufficient lime or limestone to make the slag, as well as some iron ore to assist in reducing the carbon of the iron. In about two or three hours the required amount of molten iron is brought from the mixer in ladles, and poured into the furnace on top of the scrap, lime and ore.]

[Illustration: MOLTEN STEEL BEING POURED LIKE WATER

Molten Steel Being Poured Into Ladle.

When the scrap has all been melted, a test is taken to determine the amount of carbon remaining in the bath. Iron ore is added from time to time until the carbon in the bath has been reduced to the desired point, and the metal is sufficiently hot to pour. At this point “recarburizers” (consisting of Ferro-Manganese, Ferro-Silicon, and pig-iron, or coal) are added to get the required composition. The tap hole at the back of the furnace is opened, and the steel is allowed to run out into a ladle, the slag coming last and forming a blanket over the steel in the ladle.]

[Illustration: Crane Carrying Ingot and Soaking Pit Furnaces.

The ladle is picked up by an electric crane and carried over cast-iron moulds, which are set on cars, the steel being poured into the moulds, resulting in steel ingots. A sufficient amount of time is allowed for the steel to become chilled or set, when the cars are pushed under an electric stripper, where the moulds are removed from the ingots. After the ingots leave the stripper they are taken to the scales and weighed, and after weighing are put into the soaking pits. The pits get their name from the part they play in the heating of the steel for rolling. When the steel ingot is stripped the outside of the ingot is cool enough to hold the inside, which is still in a liquid state, and the steel is put into the soaking pits to allow the inside to settle into a solid mass, after which the ingot is reheated for rolling. The length of time in the soaking pits depends upon the size of the ingot, as the larger the ingot, the greater length of time is required to set.

When the steel is ready for rolling it is taken from the pits by overhead electric cranes, and placed into a dump buggy at the end of a roller line, which leads to the blooming mill. The dump buggy derives its name from the fact that when the ingot is placed into same in an upright position, the buggy, in order to place the ingot into a horizontal position on the roller line, dumps over, in the same way as if one were to rock too far forward in a rocking-chair, the dump buggy operating on the same principle.]

[Illustration: GETTING READY TO MAKE A RAIL

Blooming Mill and Engine.

The ingot travels down the movable-roller line to the blooming-mill rolls, which roll it down from a piece 19 inches by 23 inches to what is known as an 8 inch by 8 inch bloom, which is the size usually used in the manufacture of rails. The blooming mill derives its name from the fact that after an ingot is rolled in same it is no longer called an ingot, but a bloom.

After leaving the blooming mill the bloom travels along another roller line to the shears, where it is cut into two or three pieces, the number of pieces depending on the size of the rail which is to be rolled. The blooms are then lifted over the roller line at the shears by a transfer crane, and placed on a traveling roller line which connects with the rear of the reheating furnace. This furnace is about 35 feet long, and is so constructed that when the bloom is pushed in at the rear of the furnace, another bloom drops from the front or discharge end of the furnace.]

[Illustration: THE INGOT BECOMES A RAIL

The Ingot Becomes a Rail.

The bloom dropping out, being sufficiently hot to roll into rails, travels along another roller line to the roughing or first set of rolls. Here the bloom is given five passes in the rolls, and is then transferred to the strand or second set of rolls, where it receives five additional passes; after this operation it is transferred to the finishing or third set of rolls, in which it is given one pass. The bloom has now been converted into a rail, and the rail travels on another roller line to the hot saw, where it is cut into 33-foot lengths, this being the standard length in this country for all rails. The rails when hot are cut by the hot saw to lengths of about 33 feet 6½■ inches, the allowance of inches being made for shrinkage in cooling. It is difficult to believe that steel shrinks to this extent, but this is a fact, and while the rails are cooling on the hotbeds they have the appearance of being animated, as they move first one way and then the other. After the rails are on the hotbed a sufficient length of time to cool, they are taken from the hotbed and placed on a traveling roller line, which takes them to an endless chain conveyor. The statement that rails are put on hotbeds for cooling seems paradoxical, but the hotbeds are so called because the rails are placed on them while hot, and are left there until they have cooled.

The endless-chain conveyor places the rails on another bed, from which they are picked up by an electric crane and distributed to the straightening presses, where all burrs (which have been caused by the hot-sawing operation) are removed before the rails are straightened. After straightening they are transferred to drill presses, where they have holes drilled into them for the accommodation of the splice bar, after which they are placed on the loading docks.]

[Illustration: After being carefully examined by the railroad company's inspectors they are picked up from the loading docks by electric magnets attached to a crane, and are placed in cars ready for shipment.]

Who Made the First Felt Hat?

The felt hat is as old as Homer. The Greeks made them in skull-caps, conical, truncated, narrow- or broad-brimmed. The Phrygian bonnet was an elevated cap without a brim, the apex turned over in front. It is known as the "cap of liberty." An ancient figure of Liberty in the times of Antonius Livius, A.D. 115, holds the cap in the right hand. The Persians wore soft caps; plumed hats were the headdress of the Syrian corps of Xerxes; the broad-brim was worn by the Macedonian kings. Castor means a beaver. The Armenian captive wore a plug hat. The merchants of the fourteenth century wore a Flanders beaver. Charles VII, in 1469, wore a felt hat lined with red, and plumed. The English men and women in 1510 wore close woolen or knitted caps; two centuries ago hats were worn in the house. Pepys, in his diary, wrote: "September, 1664, got a severe cold because I took off my hat at dinner"; and again, in January, 1665, he got another cold by sitting too long with his head bare, to allow his wife's maid to comb his hair and wash his ears; and Lord Clarendon, in his essay, speaking of the decay of respect due the aged, says "that in his younger days he never kept his hat on before those older than himself, except at dinner." In the thirteenth century Pope Innocent IV allowed the cardinals the use of the scarlet cloth hat. The hats now in use are the cloth hat, leather hat, paper hat, silk hat, opera hat, spring-brim hat, and straw hat.

What Is the Hottest Spot on Earth?

The hottest regions on earth is said to be along the Persian Gulf, where little or no rain falls. At Bahrein the arid shore has no fresh water, yet a comparatively numerous population contrive to live there, thanks to the copious springs which break forth from the bottom of the sea. The fresh water is got by diving. The diver, sitting in his boat, winds a great goat-skin bag around his left arm, the hand grasping its mouth; then he takes in his right hand a heavy stone, to which is attached a strong line, and thus equipped he plunges in, and quickly reaches the bottom. Instantly opening the bag over the strong jet of fresh water, he springs up the ascending current, at the same time closing the bag, and is helped aboard. The stone is then hauled up, and the diver, after taking breath, plunges in again. The source of the copious submarine springs is thought to be in the green hills of Osman, some 500 or 600 miles distant.

Where Do We Get Ivory?

Ivory is a hard substance, not unlike bone, of which the teeth of most mammals chiefly consist, the dentine or tooth-substance which in transverse sections shows lines of different color running in circular arcs. It is used extensively for industrial purposes and is derived from the elephant, walrus, hippopotamus, narwhal, and some other animals. The ivory of the tusks of the African elephant is held in the highest estimation by manufacturers; the tusks vary in size, ranging from a few ounces in weight to 170 pounds. Holtzapffel states that he saw fossil tusks on the banks of rivers of Northern Siberia which weighed 186 pounds each. Ivory is simply tooth-substance of exceptional hardness, toughness, and elasticity, due to the firmness and regularity of the dentinal tubules which radiate from the axial pulp-cavity to the periphery of the tooth.

How Did Trial by Jury Originate?

~WHY JURIES HAVE TWELVE MEN~

A jury consists of a certain number of men selected according to law and sworn to inquire into and determine facts concerning a cause or an accusation submitted to them, and to declare the truth according to the evidence. The custom of trying accused persons before a jury, as practised in this country and England, is the natural outgrowth of rudimentary forms of trial in vogue among our Anglo-Saxon ancestors. The present system of trial by jury is the result of a gradual growth under the English Common Law. There is no special reason why twelve is the usual number chosen for a complete jury except the necessity for limiting the

number. In a grand jury the number according to law must not be less than twelve nor more than twenty-three, and twelve votes are necessary to find an indictment. The ancient Romans also had a form of trial before a presiding judge and a body of judices. The right of trial by jury is guaranteed by the United States Constitution in all criminal cases, and in civil cases where the amount in dispute exceeds $20. A petit or trial jury consists of twelve men, selected by lot from among the citizens residing within the jurisdiction of the court. Their duty is to determine questions of fact in accordance with the weight of testimony presented and report their finding to the presiding judge. An impartial jury is assured by drawing by lot and then giving the accused, in a criminal case, the right to dismiss a certain number without reason and certain others for good cause. Each of the jurymen must meet certain legal requirements as to capacity in general and fitness for the particular case upon which he is to sit, and must take an oath to decide without prejudice and according to the testimony. A coroner's jury or jury of inquest is usually composed of from six to fifteen persons, summoned to inquire into the cause of sudden or unexplained deaths.

Can Animals Foretell the Weather?

Certain movements on the part of the animal creation before a change of weather appear to indicate a reasoning faculty. Such seems to be the case with the common garden spider, which, on the approach of rainy or windy weather, will be found to shorten and strengthen the guys of his web, lengthening the same when the storm is over. There is a popular superstition that it is unlucky for an angler to meet a single magpie, but two of the birds together are a good omen. The reason is that the birds foretell the coming of cold or stormy weather, and at such times, instead of searching for food for their young in pairs, one will always remain on the nest. Sea-gulls predict storms by assembling on the land, as they know that the rain will bring earthworms and larvæ to the surface. This, however, is merely a search for food, and is due to the same instinct which teaches the swallow to fly high in fine weather, and skim along the ground when foul is coming. They simply follow the flies and gnats, which remain in the warm strata of the air. The different tribes of wading birds always migrate before rain, likewise to hunt for food. Many birds foretell rain by warning cries and uneasy actions, and swine will carry hay and straw to hiding-places, oxen will lick themselves the wrong way of the hair, sheep will bleat and skip about, hogs turned out in the woods will come grunting and squealing, colts will rub their backs against the ground, crows will gather in crowds, crickets will sing more loudly, flies come into the house, frogs croak and change color to a dingier hue, dogs eat grass, and rooks soar like hawks. It is probable that many of these actions are due to actual uneasiness, similar to that which all who are troubled with corns or rheumatism experience before a storm, and are caused both by the variation in barometric pressure and the changes in the electrical condition of the atmosphere.

Nearest Approach Ever Made to Perpetual Motion in Mechanics.

An inventor has patented a double electric battery which seems to come exceedingly near to perpetual motion. Instead of using the zinc battery, he professes to have hit upon a solution which makes a battery seven times as powerful as the zinc battery, with absolutely no waste of material. The power of the battery grows gradually less in a few hours of use, but returns to its original unit when allowed to rest a few hours. He has two batteries so arranged that the power is shifted from one to the other every three hours. A little machine has been running for some years in the patent office at New York. Certain parts of the mechanism are constructed of different expansive capacities, and the machine is worked by the expansion and contraction of these under the usual variations of temperature. In the Bodleian Library at Oxford there is an apparatus which has chimed two little bells continuously for forty years, by the energy of an apparently inexhaustible "dry-pile" of very low electrical energy. A church clock in Brussels is wound up by atmospheric expansion induced by the heat of the sun. As long as the sun shines this clock will go till its works wear out. Mr. D. L. Goff, a wealthy American, has in his hall an old-fashioned clock, which, so long as the house is occupied, never runs down. Whenever the front door is opened or closed, the winding arrangements of the clock, which are connected with the door by a rod with gearing attachments, are given a turn, so that the persons leaving and entering the house keep the clock constantly wound up.

Do Plants Breathe?

Plants, like animals, breathe the air; plants breathe through their leaves and stems just as animals do by means of their respiratory organs. When a young plant is analyzed it is found to consist chiefly of water, which is all removed from the soil; there is about 75 per cent or more of this fluid present, and the rest is solid material. Of this latter by far the most abundant constituent is carbon, almost every atom of which is removed from the atmosphere by the vital action of minute bodies contained in the green leaves. The carbon is taken into the plant as carbonic acid gas. Plants also absorb oxygen, hydrogen, and nitrogen from the atmosphere in different quantities through their leaves, and also by means of their roots. These new products stored are in turn used in building up

the different organs of the plant. Plants give off used-up moisture through their leaves, just as animals perspire through the pores of their skins. Calculations have been made as to the amount of water thus perspired by plants. The sunflower, only 3½■ ft. high, with 5,616 square inches of surface exposed to the air, gives off as much moisture as a man.

What Depth of Snow Is Equivalent to an Inch of Rain?

Newly fallen snow having a depth of about 11½■ inches is equivalent to one inch of rain. A cubic foot of newly fallen snow weighs 5½■ pounds and a cubic foot of fresh or rain water weighs 62½■ pounds or 1,000 ounces. An inch of rain means a gallon of water spread over every two square feet, or about a hundred tons to every acre. The density of snow naturally varies a good deal according to the speed with which it falls. Temperature, also, has much to do with its bulk. In cold, crisp weather, when the thermometer registers several degrees of frost, snow comes down light and dry; but in moist, cold weather, when the temperature is only just below thirty-two degrees, the snow falls in large, partially thawed flakes, and occupies much less space where it falls than that which reaches the earth during the prevalence of a greater degree of cold.

How Are the Stars Counted?

Stars are counted by means of the telescope and photography. The Astronomer-Royal for Ireland, Sir Robert S. Ball, in one of his lectures mentioned a photograph which had been obtained by Mr. Isaac Roberts representing a small part of the constellation of the Swan. The picture is about as large as the page of a copy-book, and it is so crowded with stars that it would puzzle most people to count them; but they have been counted by a patient person, and the number is about 16,000. Many of these stars are too faint ever to be seen in the greatest of telescopes yet erected. Attempts are now being made to obtain a number of similar photographs which shall cover the whole extent of the heavens. The task is indeed an immense one. Assuming the plates used to be the same size as that above mentioned, it would require at least 10,000 of them to represent the entire sky. The counting of stars by the telescope was first reduced to a system by the Herschels, who introduced “star-gauges,” which were simply a calculation by averages. A telescope of 18 in. aperture, 20 ft. focus, and a magnifying power of 180, giving a field of view 15 in. in diameter, was used for the purpose. The process consisted in directing this instrument to a part of the sky and counting the stars in the field. This, repeated hundreds of times, gave a fair idea of the average number of stars in a circle of 15 in. diameter in all parts of the sky. From this as a basis it is possible to reckon the number of stars in any known area.

How Is the Volume of Sound Measured?

Sound arises from vibrations giving a wave-like motion to the surrounding atmosphere, the wave gradually enlarging as it leaves the source of disturbance, while at the same time the motion of the air particles becomes less and less. The simplest method of determining the number of vibrations of a sound is by means of Savart’s apparatus. This consists of two wheels--a toothed or cog-wheel and a driving-wheel. They are so adjusted that the cog-wheel is made to revolve with great rapidity, its teeth hitting upon a card fixed near it. The number of revolutions is indicated by a counter attached to the axis of the cog-wheel. Suppose that sound is traveling in the air at the rate of 1,000 ft. per second, and that Savart’s wheel is giving a sound produced by 200 taps on the card per second, it follows that in 1,000 ft. there will be 200 waves or vibrations, and if there be 200 waves in 1,000 ft. each wave or vibration must be 5 ft. in length. The velocity of sound through air varies with the temperature of the latter, but is usually reckoned at 1,130 ft. per second.

At What Rate Does Thought Travel?

Thought travels 111 feet per second, or about a mile and a quarter per minute. Elaborate experiments have been made by Professors Heimholtz, Hersch, and Donders, to ascertain the facts on this question, the result of which was that they found the process of thought varied in rapidity in different individuals, children and old persons thinking more slowly than people of middle age, and ignorant people more slowly than the educated. It takes about two-fifths of a second to call to mind the country in which a well-known town is situated, or the language in which a familiar author wrote. We can think of the name of the next month in half the time we need to think of the name of the last month. It takes on the average one-third of a second to add numbers containing one digit and half a second to multiply them. Those used to reckoning can add two to three in less time than others; those familiar with literature can remember more quickly than others that Shakespeare wrote “Hamlet.” It takes longer to mention a month when a season has been given than to say to what season a month belongs. The time taken up in choosing a motion, the “will time,” can be

measured as well as the time taken up in perceiving. If it is not known which of two colored lights is to be presented, and you offer to lift your right hand if it be red and your left if it be blue, about one-thirteenth of a second is necessary to initiate the correct motion.

What Is the Largest Tree In the World?

In San Francisco, encircled by a circus tent of ample dimensions, is a section of the largest tree in the world--exceeding the diameter of the famous tree of Calaveras by five feet. This monster of the vegetable kingdom was discovered in 1874, on Tule River, Tulare County, about seventy-five miles from Visalia. At some remote period its top had been broken off by the elements, or some unknown forces, yet when it was discovered it had an elevation of 240 feet. The trunk of the tree was 111 feet in circumference, with a diameter of 35 feet 4 inches. The section on exhibition is hollowed out, leaving about a foot of bark and several inches of the wood. The interior is 100 feet in circumference and 30 feet in diameter, and it has a seating capacity of about 200. It was cut off from the tree about twelve feet above the base, and required the labor of four men for nine days to chop it down. In the center of the tree, and extending through its whole length, was a rotten core about two feet in diameter, partially filled with a soggy, decayed vegetation that had fallen into it from the top. In the center of this cavity was found the trunk of a little tree of the same species, having perfect bark on it, and showing regular growth. It was of uniform diameter, an inch and a half all the way; and when the tree fell and split open, this curious stem was traced for nearly 100 feet. The rings in this monarch of the forest show its age to have been 4,840 years.

Where Did the Term Yankees Originate?

This is a word said to be a corruption of Yengees, the Indian pronunciation of English, or of the French “Anglais,” when referring to the English Colonists. It was first applied to the New Englanders by the British soldiers as a term of reproach, later by the English to Americans generally, and still later to the people of the North by the Southerners.

How Far Does the Air Extend?

It is, perhaps, generally known that enveloping the earth is a layer of air fifty or more miles in thickness. Just how thick this layer is we do not know, but we do know that it extends many miles from the earth. You may assure yourselves of this in a very simple manner by watching the shooting stars that may be seen on any clear night. These are nothing but masses of rocks that give off light only when they have been made red-hot by friction with the air in their rapid flight. The fact that we often see these stars while they are still many miles from the earth proves to us that the air through which they are passing extends to that height.

What Makes Us Feel Hungry?

Hunger is a peculiar craving which we are accustomed to say comes from the stomach. It is the business of the stomach to change such food as we take into it in such a way that the rest of the organs of the body which we have for the purpose can make blood out of it. When you feel the sensation of hunger, it means that the blood-producing system is calling on the stomach to furnish more blood-making material. The stomach prepares the food for blood production by mixing with it certain juices which the stomach is able to supply. As soon as the stomach is then called upon to supply more blood-making material, it goes to work on what is in the stomach and begins mixing things. If, however, there is nothing in the stomach, the craving which we call hunger is produced. It is, therefore, then not altogether the stomach which makes us hungry, but the parts of our body which actually turn the food into blood after the stomach has prepared it.

To prove this it is only necessary to say that the sensation of hunger will stop if food which is easily absorbed and, therefore, does not need the preparation which the stomach generally gives, is introduced into the system through other parts of the body, as, for instance, by injecting it into the large intestine, which is a part of the body, the food passes through after it leaves the stomach ordinarily.

What Makes Us Thirsty?

Thirst is a sensation of dryness and heat which is generally communicated to us through the tongue and throat. The sensation of thirst can be artificially produced by passing a current of air over the membranes which cover the tongue and throat, but thirst is naturally due to a shortage of water in the body. The human body requires a great deal of water to keep it in condition, and when

the supply becomes low a warning is given to us by making the membranes of the tongue and throat dry.

In connection with thirst, however, as in the case of hunger, where the warning is given by the stomach, thirst will be appeased by the introduction of water, either into the blood, the stomach or the large intestine, without having touched either the tongue or throat, which proves that it is not our tongue or throat that is thirsty, but the body itself.

What Is Pain and Why Does It Hurt?

Pain is the result of an injury to some part of our bodies, or a disturbed condition--a change from the normal condition. Pain is caused by nerves in the body. The network of nerves coming in big nerves from the back bone or spinal chord branches out in all directions, and near the surface of the skin they spread out like the tiny twigs of a tree, covering every point of the body. Some parts of our bodies are more sensitive than others. That is because the nerves are then nearer the surface or else there are more nerves in that part. The heel is perhaps the least sensitive part of the body, as the nerves do not lie so near the surface there.

Pain is not a thing which you can make a picture of or describe in words. Pain is a sensation of the brain caused by a disturbance of conditions in some part of the body. If you cut your finger, you cut certain veins or arteries and also the tiny nerves in the finger. The nerves immediately let the brain know that they are injured, and the brain sets to work to have the damage repaired. But there is a congestion right where the cut is. The veins being cut, the blood which would ordinarily flow through them back to the heart, pours out into the cut and the inside of your finger is thus exposed to the oxygen of the air, and the action of the air on the exposed part helps to make the pain. It is not your finger, however, that hurts. It is the shock that your brain gets when you cut your finger that hurts.

A pain in your stomach is a pain caused by something else than a cut. If the stomach could always digest everything or any amount of stuff you put in it, you would not have a stomach pain. But sometimes you put things into your stomach through your mouth, of course, that the stomach cannot handle. Or, it may be a combination of a number of things that cause this unusual condition in your stomach. The stomach makes a special effort to get rid of this troublesome substance and generally succeeds eventually, but while the fight is going on, it pains or hurts you.

Pain is the result of a disturbance of the nerves. It is just the opposite of gladness. We sometimes are so glad we feel good all over. Pain is just the opposite. You can prove that pain is not a real thing but only a sensation. Perhaps you have had toothache. You go to the dentist and he kills the nerve or takes it out. After that you cannot have the toothache in that tooth again, because there is no nerve there to telegraph to the brain, even though the cause of the hurt still exists. You cannot feel pain unless the brain knows about the injury.

What Is the Horizon?

Of course you know what the horizon is. It is easiest to see the horizon at sea when out of sight of land. There, when you look in any direction from the ship to the place where the sea and the sky meet you see a line which, if you follow with your eye as you turn completely around, makes a perfect circle. It looks as though it marked the boundary of the earth. On land it is not easy to see as much of the horizon at one time, because of buildings and trees and hills in the woods and elsewhere, but if the land were perfectly smooth like the sea and there were no trees or buildings or hills in the way, you could see just as perfect a circle on land as on sea. This proves that the horizon is a movable circle. On land it is where the earth and sky appear to meet, and on water it is where sky and water appear to meet.

How Far Away Is the Horizon?

The actual distance of the horizon away from us depends altogether upon the height above the sea level from which we are looking as far as we can. The horizon is always as far away as we can see. At the seashore, where we are practically on a level with the water, we cannot see so far as when we are up on a bluff or hill overlooking the sea. The higher we go up straight from a given point the greater the distance we can see up to a certain point and the farther away the horizon will appear. The height of the person looking, of course, figures in this, because when you are at sea level it is only your feet really that are at sea level (if you are standing up straight) and the distance of the horizon is measured from the eye of the person looking. A boy or girl of ten would be, say, a little over four feet high, and the eyes of such a person would be about four feet above the level of the sea. At that height the horizon would be about two and a half miles away. If the eyes are six feet above sea level the distance of the horizon will be about

three miles, so that practically every one sees a different horizon, that is, one that appears at a different distance. A hundred feet above the level of the sea the horizon will be more than thirteen miles away, while at 1000 feet altitude it would be 42 miles away, and if you could go a mile into the air the horizon would appear 96 miles from where you are. The higher you go the farther away the circle which apparently marks the joining of the earth and sky appears.

Why Can We See Farther When We Are Up High?

Remember that the earth is round and you will probably be able to answer the question yourself. This one, like most questions boys and girls ask, only requires a little thought. The earth, of course, as we have learned long ago, is a globe. When you look out on the land or the sea from a high place you can see more of the earth's round surface before the curve of the earth's surface takes things beyond the range of vision. If you are on a bluff 100 feet high at the seashore and looking toward a point where a ship is coming toward shore, you will be able to see the ship much sooner than if you were at the sea level. In exact words, you actually see more of the earth's surface the higher up you are, because, as you go up your position in relation to the curvature of the earth's surface changes.

What Makes Lobsters Turn Red?

When a lobster is taken out of the lobster trap with which the fisherman traps him, he is green, but when he comes to the table as a choice morsel of food his shell is red. We know that he has been boiled and we know that he goes into the boiling water green and comes out red. This change in the color of the shell of the lobster is the result of the effect of boiling water on the coloring material in the shell. When the lobster is put in the boiling water the process of boiling produces a chemical change in the color material in the lobster's shell. There is no particular reason why the lobster should turn red, excepting that that is the effect boiling water has on the coloring matter in the shell.

Why Do We Have to Die?

Death must come to all things that have life. All matter in the world is either living (animate) or dead (inanimate). Inanimate things do not change. They remain always the same. We can change the form and size of inanimate things, and particles of them even help to make up the bodies of the living things, but what they are made of always remains what it was.

Death is one of the things that must occur if we are to continue to have more life. The whole plan of living things includes the ability to reproduce themselves. Every kind of life has the power to produce life like itself and this process of reproduction is continuous. If there were no death, then the world would soon be crowded with living things to the point where there would be neither room nor food.

Making Plate Glass

What Is the Difference Between Plate Glass and Window Glass?

How is plate glass made? These questions are asked very frequently. The two products are wholly unlike each other; and we wish to show wherein lies the difference. We shall tell how plate glass is made; and we hope to make it clear that great care, time and expense are involved in its manufacture.

The raw materials may be said to be virtually the same in plate glass as in window glass; the main difference being that in plate glass greater care is exercised in selecting and purifying the ingredients. Window glass is made with a blow-pipe. The work requires skill on the part of the operator; but the process is quite simple and rapid. And the result is, naturally, a comparatively ordinary and indifferent product. On the other hand, the superb quality of plate glass is owing to the elaborate method of producing it.

Commercial plate glass was first made in France somewhat more than two hundred years ago; although glass in one form or another has been in use for many centuries. Apparently glass was known in Egypt fully four thousand years ago.

[Illustration: MINING SILICA]

The materials used are silica (white sand), carbonate of soda (soda ash), and lime. Other materials, as arsenic and charcoal, are used in small proportions, but the main ingredients are the first three named.

Probably it is little imagined that in the production of plate glass, mining is involved in two or more forms (namely silica and coal), also the quarrying of limestone, the chemical manufacture of soda ash on a large scale, the reduction and treatment of fire clay to its right consistency, an elaborate and expensive system of pot making; and the melting, casting, rolling, annealing, grinding and polishing of the glass.

In special uses, as in beveled plates and mirrors, two more elaborate processes must be added--beveling and silvering--all of which are performed under the direction of experts aided by a large amount of labor and expensive machinery.

Pots of fire clay take so important a part in the successful manufacture of plate glass that the subject deserves especial notice. The different clays after being mined are exposed to the weather for some time to bring about disintegration.

~THE CLAY MUST BE TRAMPLED WITH BARE FEET~

At the proper stage finely sifted raw clay is mixed with coarse, burned clay and water. This reduces liability of shrinkage and cracking. It is then “pugged,” or kneaded in a mill; kept a long time (sometimes a year) in storage bins to ripen; and afterwards goes through the laborious process of “treading.” Nothing has thus far been found in machinery by which the right kind of plasticity can be developed as does this primitive treading by the bare feet of men. The clay must be treaded, not once or twice, but many times. The building of pots is a slow, tedious and time-killing affair; but this is most essential.

~HOW MELTING POTS ARE MADE~

Without extreme care, some elements used in the making of the pots might be fused into glass while undergoing the intense heat of the furnace; or they might break in the handling. The average pot must hold about a ton of molten glass, and the average furnace heat necessary is about 3,000° Fahrenheit. The work is not continuous. Each workman has several pots in hand at a time, and passes from one to another adding only a few inches a day to each pot, so that a proper interval for seasoning be given. After completion, comes the proper drying out of the pots; and this is another feature in which the greatest scientific care is required. No pot may be used until it has been left to season for at least three months, and even a year is desirable. And after all this trouble, the pot has but 25 days of usefulness. The pots form one of the heavy items of expense in plate glass manufacture; and upon their safety great things depend.

[Illustration: POT MAKING.]

[Illustration: MIXING THE CLAY.

TRAMPLING THE CLAY.]

[Illustration: SKIMMING THE POT.]

[Illustration: CASTING PLATE GLASS.]

~HOW THE HUGE PLATES OF GLASS ARE CAST~

The pot, having been first brought to the necessary high temperature, is filled heaping full with its mixed “batch” of ground silica, soda, lime, etc. Melting reduces the bulk so much that the pot is filled three times before it contains a sufficient charge of metal. When the proper molten stage is reached the pot is lifted out of the furnace by a crane; is first carefully skimmed to remove surface impurities, and then carried overhead by an electric tramway to the casting table. This is a large, massive, flat table of iron, having as an attachment a heavy iron roller which covers the full width, and arranged so as to roll the entire length of the table. The sides of the table are fitted with adjustable strips which permit the producing of plates of different thicknesses. The pasty, or half-fluid glass metal is now poured upon the table from the melting pot, and the roller quickly passes over it, leaving a layer of uniform thickness. The heavy roller is now moved out of the way, and then by means of a stowing tool the red hot plate is shoved into an annealing oven. All of these stages of the work have to be performed with remarkable speed, and by men of long training and experience. The plates remain for several days in the annealing oven, where the temperature is gradually reduced from an intense heat at first, until at the end of the required period it is no hotter than an ordinary room.

[Illustration: PREPARING THE GRINDING TABLE.]

When the plate is taken from the annealing oven it has a rough, opaque, almost undulating appearance on the surfaces. It is only the surface, however, for within it is as clear as crystal. First, it is submitted for careful inspection, so that bubbles or other defects may be marked for cutting out. It then goes to the cutter who takes off the rough edges and squares it into the right dimensions; and thence to the grinding room.

[Illustration: HOW THE GLASS PLATES ARE GROUND

GRINDING THE PLATES]

The grinding table is a large flat revolving platform made of iron, twenty-five feet or more in diameter. The plate must be carried from the annealing oven to the grinding machines, and thence to the racks, by men skilled in the art. Twenty men are required to carry the larger plates of glass, ten on each side, using leather straps and stepping together in perfect time. The lock-step is absolutely essential to prevent accident. The grinding table is prepared by being flooded with plaster of Paris and water; then the glass is carefully lowered, and a number of men mount upon the plate and tramp it into place until it is set. After this, greater security is obtained by pegging with prepared wooden pins; and then the table is set in motion. The grinding is done by revolving runners. Sharp sand is fed upon the table, and a stream of water constantly flows over it. After the first cutting by the sand, emery is used in a similar manner.

The plates are inspected after leaving the grinding room, and if any scratches or defects of any kind are found they are marked. Some of these can be rubbed down by hand. There are also, not infrequently, nicks and fractures found at this stage; and in such case the plate must again be cut and squared. Afterward comes the polishing, which is done on another special table. The polishing material is rouge, or iron peroxide, applied with water, and the rubbing is done by blocks of felt. Reciprocating machinery is so arranged that every part of the plate is brought underneath the rubbing surface.

The grinding and polishing has taken away from the original plate half of its thickness, sometimes more. There is no saving of the material; it has all been washed away. When to this waste is added the fact that fully half of the original weight of lime and soda has been released by the heat of the furnace, escaping into the atmosphere in fumes and acids, one may begin to understand something of the cost of converting the rough materials of sand, limestone and soda into beautiful plate glass.

~HOW MIRRORS ARE MADE~

In preparing plate glass for mirrors great care must be exercised in the selection of the plates. This selection bears reference not only to surface defects, but to the quality in general; defects which cannot ordinarily be seen are magnified many fold after the glass has received a covering of silver.

[Illustration: BEVELING PLATES]

In the process of beveling, the plate passes through the hands of skilled workmen of five different divisions, namely: roughers, emeriers, smoothers, white-wheelers and buffers; and different abrasive materials are used in the order indicated by the titles. These materials are sand, emery, natural sandstone imported from England, pumice and rouge.

The roughing mill is a circular cast-iron disk about 28 inches in diameter, constructed so that the face or top of the mill revolves upon a horizontal plane at a speed of about 250 revolutions per minute. The sand is conveyed to the mill from above through a hopper simultaneously with a stream of water which is played upon the sand to carry it to the mill. The rougher places the edge of the plate upon the rapidly revolving mill, and the cutting of the bevel is done by the passage of the sand between the mill and the plate of glass. A bevel of any desired width may be produced. Pattern plates containing incurves, mitres, etc., require a practiced eye and great skill upon the part of the operator.

When the plate leaves the rougher’s hands the surface of the bevel has been ground so deep by the coarse sand that polishing at this stage is impossible. Consequently, in order to produce a surface fine enough to render it susceptible of a high and brilliant polish it must go through the various treatments we have mentioned. The emerier uses a fine grade of emery on a mill similar in construction to a roughing mill, which takes away considerable of the coarse surface given by the first cutting. Then it goes to the smoother, who reduces the roughness slowly by using a fine sandstone from England; then it goes to the white-wheeler who operates an upright poplar-wood wheel using powdered pumice stone as an abrasive; and then, as a last stage it reaches the buffer, whose method of operation is shown in the illustration. The buffer brings a high polish to the bevel by the use of rouge

applied to thick felt which covers his wheel.

[Illustration: SILVERING MIRROR PLATES.]

[Illustration: The two photographs here are of the same building taken under contrasting conditions. The first picture was taken through a window glazed with common window glass. It is an extreme example, to be sure, but of a sort not infrequently seen. The second view shows the same building taken through a window of polished, flawless plate glass. An observing person can see this startling contrast any day as he walks along a residence street. At intervals a front window will be seen which gives a twisted, distorted reflection of the houses or trees on the opposite side: this is window glass. The other kind--the window that gives a sharp brilliant reflection--is _plate glass_. It is practically impossible to obtain superior reflecting quality from window glass. It can only be had from surfaces which have been ground and polished.]

The plate, after leaving the beveling room, is again carefully examined for surface defects. These defects may consist of scratches caused inadvertently by permitting the surface of the plate to come into contact with the abrasive material. These scratches are removed by hand polishing, which must be skillfully done; otherwise the reflection will become distorted through over-polishing in a given area or spot. The plate is then taken to a wash table where the surface to be silvered is thoroughly washed with distilled water; after which it is taken to a table that is covered with blankets, and which is heated to a temperature of from 90° to 110°. The blanketing is to protect the plate from being scratched, and also to catch all of the silver waste. The silvering solution is nitrate of silver liquefied by a certain formula, and is poured over the plate; the fluid having an appearance which to the ordinary observer looks like nothing other than pure distilled water. Within a few minutes the silver, aided by a reactory, added prior to pouring, begins to precipitate upon the glass; the liquids remaining above, and thus preventing air and impurities from coming into contact with the silver. Such contact would produce oxidation. After the silver is precipitated the plate is thoroughly dried, shellacked and painted; after which it is ready for commercial use.

Until about 25 years ago, practically all mirrors were silvered with mercury. There have been two reasons for discouraging the use of mercury for silvering; one being its injuriousness to the health of the workmen. In some European countries stringent laws were enacted, stipulating that men should work only a certain number of hours.

Other hygienic stipulations, added to the fact that the use of mercury was already very expensive, have tended to replace that process by the use of nitrate of silver.

Why Is the Sky Blue?

This question puzzled every one who thought of it for a long time. Even astronomers, the men who make a business of studying the skies, and other learned men, puzzled their brains about it and searched for the answer long ago, until finally, as always happens when a lot of people study a subject, Professor John Tyndall, a noted scientist of the last century, discovered the answer. The explanation follows: All the light we have is sunlight, which is pure white light. This white light is made up of rays of light of different colors. These rays are red, orange, yellow, green, blue, indigo and violet. It takes all of these different rays of light to make our white sunlight, and when you separate sunlight into its original rays you always produce the rays of light in the above colors and in the same order. This is only true, however, when the sunlight is passed through an object which does not absorb any of its rays. This is the arrangement of the different colors of light found in the rainbow. The rainbow is formed by sunlight passing into raindrops or vapor in such a way as to divide the sunlight into the different colored rays of light. When the rainbow is formed none of the rays are absorbed by raindrops or vapor through which the sunlight passes. Some of these rays of light are known as short rays and others as long rays. But when sunlight meets other things besides those which make a pure rainbow, these other objects have the ability to absorb some of the rays of colored light, and they throw off the remainder. When these rays have been thrown off those which have been absorbed make many different combinations, and thus are produced all of the different colors we know, the various tints and shades of color, according to composition and size.

Now, then, to get back to the color of the sky, which is blue as we know. The sky or air which surrounds the earth is filled with countless tiny specks of what we may call dust--particles of solid things hanging or floating in the air. These specks are of just the size and quality that they catch and absorb part of the rays of light which form our sunlight and throw off the rest of the rays, and the part which has been absorbed forms the combination of color which makes our sky so beautifully blue. Sometimes you notice, of course, that the sky is a lighter or darker blue than at other times. This difference is due to the kind and condition of tiny specks in the air at the time, and to the direction or angle at which the sunlight strikes these tiny particles. This fact brings up a question which

you have not asked, but which would come naturally as the result of your first.

What Makes the Colors of the Sunset?

The direction of the sun's rays when they meet these large and small particles in the air has a great deal to do with the combination of colors that result as these objects absorb part of the rays and throw off others. The sky is the most beautiful blue when the sun is high in the sky. But when the sun is setting the light has a greater distance to travel through the belt of air which surrounds the earth than when it is high up over our heads. You know that if you stick a pin straight down into an orange it won't go in very far before it is clear through the peel, but if you stick the pin into an orange along the edge it will go through a great deal more of the peel than the other way. That is the way it is with the sunset colors. The peel of the orange is a good representation of the belt of air which surrounds the earth. At sunset the light instead of coming straight down through the belt of air, thus meeting the eye through the shortest possible amount of air, strikes the air on a slant, and, therefore, travels through a great deal more air and closer to the earth to reach it, with the results that it meets a great many more of these little specks, besides all the smoke and other things that hang in the air near the ground, and we thus get many more colors, because some of the things in the air absorb some of the rays and others absorb very different rays when the light comes in this slanting way, and that is what makes the different colors in the sunset. For this reason sunsets are often richer and more beautiful in color when the air is not so pure, but has much dirt and other matter floating about in it.

Are There Two Sides to the Rainbow?

No, there is only one side to the rainbow. The rainbow is made by reflection of the rays of sunlight through drops of water in the air, but you can never see a rainbow unless you are between it and the sun. You could never see a rainbow if you were looking at the sun, and so if you are looking at a rainbow you can be certain that anyone on the other side of it could not see it, because they would have to be looking right at the sun. The rainbow is always opposite to the sun and there can never be two sides to it.

Do the Ends of the Rainbow Rest on Land?

The ends of the rainbow do not rest on anything. You see, the rainbow is only the reflection of the sun's rays thrown back to us by the inside of the back of the raindrops, which are still in the sky after the rain. Of course, if any of the drops of water touched the ground they would cease to be raindrops and, therefore, could not reflect the rays of the sunlight. So, what we think of as the ends of the rainbow do not really exist at all. The rainbow is only a reflection of the rays of sunlight from countless drops of water in the air, which the sun's rays must strike at a certain angle in order to reflect back the light so we can see it. Where the sun's rays do not strike the drops of water at the right angle no light is reflected, and there is the end of the rainbow.

What Causes the Different Colors of the Rainbow?

The colors of the rainbow, which are always the same, and are shown in this order--red, orange, yellow, green, blue and violet--are sunlight broken up into its original colors. It takes all of these colors in the proportions in which they are mixed in the rainbow to make the pure sunlight. These are known as the prismatic colors. As shown in another answer to one of your puzzling questions, the rainbow is caused by the rays of the sun passing into drops of water in the air and reflected back to us with one part of the drop of water acting on it in such a way as to break up the pure sunlight into these prismatic colors. When a rainbow appears at a time when there is a great deal of sunlight, you will generally see two rainbows. The inner rainbow is formed by the rays of the sun that enter the upper part of the falling raindrops, and the outer rainbow is formed by the rays that enter the under part of the raindrops. In the inner or primary bow, as it is called, the colors beginning at the outside ring of color are red, orange, yellow, green, blue and violet, and being exactly reversed in the outer or secondary bow. The secondary bow is also fainter. You may sometimes see smaller rainbows, even if it has not been raining, when looking at a fountain or waterfall. These are caused in exactly the same way.

What Makes the Hills Look Blue Sometimes?

This is due to the fact that when the hills look blue you are looking at them at a distance, and there is a long stretch of air between you and the hills. This air is filled with countless particles of dust and other things, and what you see is not really blue hills, but the reflection of the sun's rays from the little particles in the air striking your eye. The color is due to the angle at which the light from the

sun strikes these particles, and is reflected back to your eye and partially due to the character of the particles in the air.

Do the Stars Really Shoot Down?

The answer is “No.” We have come to use the expression “shooting stars” commonly, but we should probably be more correct if we said “shooting rocks,” for the things we refer to commonly as “shooting stars” are more like rocks than anything else. If any of the real stars were to fall into the air surrounding the earth we should all be burned up by the great heat developed long before it actually hit the earth, which it would undoubtedly destroy.

The things that fall and leave a streak of light are really only pebbles, stones, rocks or pieces of iron and other substances that fall from some place into the earth’s air belt. When they strike the air at the speed at which they are falling the friction of the air makes a heat that causes them to become luminous, and by far the greater part of them is burned up before they get very near the earth. We call them meteorites. Sometimes, though rarely, one will manage to strike the earth, coming at such great speed and being so large that the air has not been able to burn it up completely, and it will strike the earth and sink deep down into the soil. In most museums can be seen such meteorites that have been dug up after striking the earth. These are constantly falling into the air surrounding the earth, but in the day-time their light is not strong enough to be seen while the sun is shining.

Will the Sky Ever Fall Down?

No, the sky can never fall down, because it is not made of the kind of things that fall. We have become used to thinking of it as the roof of the earth, a great dome-shaped roof, because in our little way of looking at things we compared the earth and what is above it with the houses in which we live. The sky is just space in which the heavenly bodies revolve in their orbits. We cannot really ever see sky. We see only the sun’s light reflected by the air belt which surrounds the earth. In this air belt are the clouds which do come closer to the land at times than at others, and this is apt to aid in giving us an incorrect impression of this.

What Is the Milky Way?

The “Galaxy,” or “Milky Way,” as it is popularly called, is a luminous circle extending completely around the heavens. It is produced by myriads of stars, as can be seen when you look at it through a telescope. It divides into two great branches at one point, which travel for some distance separately and then reunite. It has also several branches. At one point it spreads out very widely into a fanlike shape.

Why Do They Call It the Milky Way?

The stars in the group are so numerous that they present to the naked eye a whiteness like a stream of milk. To produce this effect there are not hundreds of stars, nor thousands of them, but actually millions of them.

When you stop to think that each one of these stars in the Milky Way is a sun like our own--some of them smaller, of course, but many of them much larger--you begin to realize how impossible it is for man to form any real idea of the magnitude and wonders of the earth. Here in the Milky Way are so many suns like our own sun that they together as we look at them form the particles of a path which makes the circle of the heavens, and yet are so far away that to the naked eye each of them looks to us like only one of countless drops of milk in a very large stream of milk that goes around the whole sky.

Why Don’t the Stars Shine in the Day-time?

The stars do shine in the day-time. If you will go down into a deep well or the open shaft of a deep mine and look up at the sky, of which you can see a circular patch at the top of the well, you will be able to see the stars in the day-time. The moon also shines in the day-time, on some part of the earth. At certain times during the month you can notice that the moon rises before the sun sets, and sometimes in the morning you can still see the moon in the sky after the sun is up. Usually you cannot see either the moon or the stars in the day-time, because the light from the sun is so bright and strong that the light of the stars and moon are lost in the brightness of the sun’s rays. When the moon is visible before the sun sets or after the sun has risen it is because the light of the sun is not so bright and strong at the beginning or close of daylight. If you are fortunate enough some time to witness a total eclipse of the sun you will be able to see the stars in day-time without having to go down into a deep well or mine shaft.

How Far Does Space Reach?

Space surrounds all earths, planets, suns, and extends for an infinite distance beyond each of them in all directions. It is impossible to measure in terms of human knowledge how far space extends. It is one of the things beyond the comprehension of the human mind, and for that reason man can never know in miles or the number of millions of miles how far it extends. Man has been able to measure the distance from the earth of some of the stars, and some of the nearest of them are millions of miles from the earth. Most of them are hundreds and even thousands of million miles away, and when we stop to think that space extends at least as far on the other sides of the stars as it does on this side, and even beyond that, we can readily understand that it is not only impossible to measure space, but also impossible to give in words any conception of what its limits might be.

There is one word--infinite--which we are forced to use in speaking of the extent of space. Infinite means “without end,” unbounded, and so man has come to use the word “infinite” in describing the extent of space, and that is as near as any one can describe it.

What Does Horse Power Mean?

The term “horse power” is used in describing the amount of power produced by an engine or motor. When man made the first engines he needed some term to use in describing the amount of power his engine could develop. Up to that time man had used the horse for turning the wheels of his machinery and the horse to him naturally represented the most powerful animal working for man. When engines came into use they replaced the horses because they were capable of developing many times the power of the horse. In finding an expression which would accurately convey to the mind of another the power of a particular engine, it was natural to say that this engine would do the work of five, ten or more horses, and as this described it accurately and in a way that was entirely clear, it became customary to describe the power of an engine as so many times the power of one horse.

To-day we still cling to the term “horse power” in describing the strength of the engine, although the horse-power unit used to-day is greater than the power of an average horse. To speak of an engine of one horse power to-day means an engine that has the power to lift 30,000 pounds one foot in one minute.

[Illustration: WHERE OUR COAL COMES FROM

A COAL BREAKER.

Coal is brought in mine cars from several mine shafts and slopes, dumped onto a conveyor that runs on the inclined framework shown at the right of the picture. At the top it is broken in rolls, sorted and sized as it slides through the different screens, pickers, etc., and is finally delivered into railroad cars.]

The Story in a Lump of Coal

How Did the Coal Get Into the Coal Mines?

The heavy black mineral called coal, which we burn in our stoves and furnaces, and use to heat the boilers of our engines was formed from trees and plants of various sorts. Most of the coal was formed thousands of years ago at a time when the atmosphere that envelopes the earth contained a much larger proportion of carbonic acid gas than it does now, and the climate of all regions of the earth was much warmer than it now is. This period was known as the carboniferous age, that is, the coal-making age, and its atmospheric conditions, favored the growth of plants, so that the earth was covered with great forests, of trees, giant ferns, and other plants, many of which are no longer found on the earth. In the warm, moist, and carbon-laden atmosphere of that period the growth of all kinds of plants was rapid and luxuriant, and as fast as old trees fell and partially decayed, others grew up in their places. In this way, thick layers of vegetable matter were formed over the soil in which the plants grew. In many places, where these beds were formed, the surface of the earth became depressed and the water of the sea flowed over the beds of vegetable matter.

Sediment of various kinds was deposited over the vegetable matter, and in the course of centuries the sediment was transformed into rock.

After the formation of the covering of sediment, the decay of the vegetable matter was checked, but a slow change of another kind was brought about by the pressure of the sedimentary deposits and the heat to which the plant remains were subjected. The

hydrogen and oxygen which constituted the greater part of the plant substance was driven off and the carbon left behind. This change took place very gradually, through periods so long that we can only guess at their duration, but we know that many beds of coal were formed from layers of vegetable matter that were covered up many thousand years ago.

[Illustration: MINE WORKERS THAT NEVER SEE DAYLIGHT

Underground stable constructed of concrete and iron, with natural rock roof to avoid danger of fire. Mules are only taken to surface when mines are idle.]

The coal first formed and submitted longest to pressure is known as hard coal, or anthracite. It is pure black, or has a bluish metallic luster. Its specific gravity is 1.46; which is about the same as that of hard wood. Anthracite contains from 90 to 94 per cent. of carbon, the remainder being composed of hydrogen, oxygen, and ash.

[Illustration: The Mules and their drivers.--An important part of the haulage system. Mules are kept in stables on surface at this mine and driven in every day through slope or drift.]

Hard coal may be called the ideal fuel and is especially adapted to domestic heating purposes. It burns without smoke and produces great heat. There is no soot deposit upon the walls of chimneys, and in good stoves or furnaces the small amount of gas given off by it is consumed. Anthracite is the least abundant of all the varieties of coal and is much more costly than the other varieties. For this reason it is not much used in manufacturing.

[Illustration: HOW THE SLATE PICKERS WORK

Boy slate pickers. Coal slides down the chutes. Boys pick out the slate and rock and throw into chute alongside.]

[Illustration: Spiral slate pickers do work of many boys. Coal and rock start together at the top in the small inner spiral. The coal being lighter slides faster, and in going around is carried over the edge into the outer spiral, while the rock continues in the bottom.]

The coal formed later is very different in composition and is called bituminous or soft coal. Its name is derived from the fact that it contains a soft substance called bitumen, which oozes out of the coal when heat is applied to it. Soft coal contains from 75 to 85 per cent. of carbon, some traces of sulphur, and a larger percentage of oxygen and hydrogen than anthracite. When soft coal is heated in a closed vessel or retort, the hydrogen and oxygen, in combination with some carbon, are driven off.

[Illustration: HOW A COAL MINE LOOKS INSIDE

Shaft gate. One of the two cages in the shaft has just brought the men to the surface; the other is at the bottom. Safety gate resting on top of cage covers top of shaft when cage is down, as shown at right.]

[Illustration: Section showing Anthracite Seams. Coal is shown black; rock and dirt lighter; shaft tunnels and workings, white. Upper part of “Mammoth” seam is stripped and quarried.]

[Illustration: Lignite mine in Texas. Loaded mine cars ready to go to surface.]

[Illustration: HOW THE MINERS LOOSEN THE COAL

Undercutting with pick. The man lying on his side cuts under the coal. A light charge of powder exploded in a drill hole near the roof breaks the coal down in large pieces.]

Soft coal is black, and upon smooth surfaces it is glossy. It lacks the bluish luster sometimes seen in hard coal and is much softer and more easily broken. When handled it blackens the hands more than hard coal does. In this kind of coal are frequently seen the outlines of leaves and stems of plants that enter into its formation. Occasionally, trunks of trees with roots extending down into the clay below the bed of coal have been found.

[Illustration: Undercutting in seam. A compressed air driven machine undercuts deeper and faster than the man with a pick.]

Soft coal has a specific gravity of 1.27. It burns with a yellow flame which is larger than the flame from hard coal, but it does not emit so high a degree of heat. Combustion, generally imperfect, gives rise to offensive gases and to black smoke that concentrates in the air and falls to the ground as soot, which blackens buildings, and, in winter, noticeably discolors the snow.

The formation of lignite has been observed in the timbers of some old mines in Europe. In some of these mines wooden pillars have been supporting the rocks above for four hundred years or longer, and in that time the pressure of the rocks and other influences acting upon the wood of the pillars have caused it to become transformed into a brown substance resembling lignite. This fact tends to confirm the theory of coal formation stated at the beginning of this article. The proportion of carbon in lignite is never above 70 per cent., and the ash indicates the presence of considerable earthy matter. It is chiefly used in those forms of manufacture where a hot fire is not required. In Europe it is used, to some extent, in heating the houses of the poorer classes.

Peat is regarded as the latest of the coal formations. In it, the change in the vegetable matter has not extended beyond merely covering it, and subjecting it to slight pressure.

Peat is formed in marshy soils where there is a considerable growth of plants that are constantly undergoing partial decay and becoming covered by water. It consists of the roots and stems of the plants matted together and mingled with some earthy material. When freshly dug out of the bog or marsh in which it was formed there is always a quantity of water in it, the amount being greatest in the peat found nearest the surface and least in that at the bottom of the bed, where the peat is not very different in appearance from lignite.

Peat is used for fuel where wood is scarce and coal is high in price. Recent experiments in saturating peat with petroleum, have shown that in this way a form of fuel may be produced for which considerable value is claimed. Its manufacture is confined to Southern Russia, where peat is plentiful and petroleum is cheap.

Why Does Firedamp Explode in a Safety Lamp Without Producing an Explosion of the Gas With Which the Lamp Is Surrounded?

The passing of the flame from the lamp to the outside air is prevented by the gauze. This splits the burning gas into little streamlets (784 to each square inch of gauze), which are cooled below the point of ignition, that is, are extinguished by coming in contact with the metal of the gauze, so that the flame does not pass outside the lamp. In some cases the explosion may be so great as to force the flame through the gauze and thus ignite the gas outside.

Are There Any Conditions Under Which it Would Not Be Safe to Use a Safety Lamp?

~THE DANGERS TO THE MINERS~

The underground conditions affecting the safety of the lamp are exposure in air-currents of high velocity by reason of which the flame may be blown through or against the gauze, or exposure for too great a time to mixtures of air and gas which will burn within the lamp and thus heat the gauze. The dangerous velocity of air-currents begins at about 500 feet a minute, but varies with the type of lamp, some being much less sensitive to air-currents of high velocity than others. Other conditions under which the lamp is not safe concern the lamp itself or the one using it. The lamp is dangerous in the hands of inexperienced persons or when the gauze is dirty or broken. If the gauze is dirty, that portion absorbs the heat and may become hot enough to ignite the outside gas; naturally any holes in the gauze will pass the flame.

The safety lamp when left too long in air containing much explosive gas may cause an explosion, and it is extinguished by certain unbreathable gases. The electric lamp burns safely regardless of the atmosphere, but gives no warning of poisonous or explosive gases. It is often used by rescue men wearing oxygen helmets to enter mines full of poisonous gases after explosions.

[Illustration: THE LAMP WHICH SAVES MANY LIVES

The safety lamp. The sheet iron bonnet or covering of the upper part protects the gauze within from strong currents of air, while the glass permits the light to be diffused. The above is a modern lamp similar to a bonnetted Clanny lamp.]

The safety lamp is dangerous when there is a hole in the gauze that will permit the passage of flame to the outside, or when the gauze is dirty, so that any particular spot may be overheated, or when the velocity of the air is so great that the flame is blown through the gauze, or (generally) when in the hands of an inexperienced person. The unbonneted Davy lamp is not safe where the velocity of the air exceeds 360 feet per minute. The velocity with which the air strikes a lamp carried against it is increased by the amount equal to the rate at which the fireboss travels. If he walks at the rate of, say, 4 miles an hour or 352 feet a minute (on the gangways he will usually have to move faster than this to make his rounds on time) he will create by his own motion (and in still air) a velocity practically the same as that at which the unbonneted Davy is considered unsafe.

[Illustration: Open oil lamp commonly worn on hat. Wick is inverted in spout.]

[Illustration: Acetylene or carbide lamp for cap or hand.]

History of the Safety Lamp.

The safety lamp, the miner's faithful and indispensable companion at his dangerous work, has been, heretofore, considered as the invention of the famous English scientist, Humphrey Davy, though the name of George Stephenson, of locomotive fame, has also been mentioned in this connection. Both came out with their inventions about the same time, but neither of them is the real inventor of the safety lamp; for there was, as proven by Wilhelm Nieman, a safety lamp in existence two years before Davy's invention became known. It was not inferior to the latter, but rather surpassed it in illuminating power. Previous to this, all the precaution employed for the prevention of the threatening dangers of firedamp had been quite incomplete. One tried to thoroughly ventilate the mines by fastening a burning torch to a large pole, which was pushed ahead and exploded the gases. This was extremely dangerous work which, in the Middle Ages, was generally done by a criminal, in order that he might atone for his crimes, or by a penitent for the benefit of mankind. The attempt to substitute for the open light phosphorescent substances, encased in glass, was not much of a success. An improvement was the so-called steel mill, invented about 1750 by Carlyle Spedding, manager of a mine. This steel mill consisted of a steel wheel which was put into rapid motion by means of a crank. By pressing a firestone against the fast revolving wheel, an incessant shower of sparks was produced giving a fairly good and absolutely safe illumination. However, the running expenses of his apparatus, which necessitated the continual services of one man, were very high; for instance, the expenditure for light in a coal mine near Newcastle in the year 1816 amounted to about $200 per week. Nevertheless, the steel mill was very much appreciated and in use for a long time, only to be slowly supplanted by the safety lamp.

[Illustration: ELECTRIC CAP LAMP AND BATTERY.

The safety lamp when left too long in air containing much explosive gas may cause an explosion, and it is extinguished by certain unbreathable gases. The electric lamp burns safely regardless of the atmosphere, but gives no warning of poisonous or explosive gases. It is often used by rescue men wearing oxygen helmets to enter mines full of poisonous gases after explosions.]

~THE MAN WHO INVENTED THE SAFETY LAMP~

At the beginning of the nineteenth century the existing coal mines were worked to the limit and the catastrophies, caused by firedamp, increased in an alarming manner. In fact the distress was so great that in 1812 a society for the prevention of mine disasters was formed at Sutherland, and the origin of the safety lamp can be traced back to the efforts and labors of this organization. Dr. William Reid Clanny, a retired ship's surgeon, was probably the first to undertake the task (in the year 1808), which he successfully finished with energy and skill. He concentrated his efforts at first on the separation of the flames from the surrounding atmosphere, but he did not succeed till the latter part of 1812, when he constructed a lamp that seemed to meet all requirements. The report of this invention was submitted to the Royal Society of London, May 20, 1813, and was printed in the minutes of that academy. The casing of this original safety lamp was closed at the top and bottom by two open water tanks; the air was pumped in by means of bellows and, passing in and out, had to go through both these reservoirs which acted as valves, so to speak. The lamp proved to be absolutely safe and was successfully introduced by the management of Herrington Mill pit mine. The clumsy parts of this apparatus were eliminated by its inventor by various improvements. The so-called steam safety lamp was completed in December, 1815, and installed in several mines. In the meanwhile, two competitors made their appearance. George Stephenson had finished his lamp October 21, 1815, and Davy published his first experiments November 9, 1815, in the Transactions of the Royal Society of London. Clanny's lamp, nevertheless, stood the test in the face of this competition, through its much superior illuminating power, and more particularly as it still continued to burn when the Davy and Stephenson lamps had gone out. To Clanny, therefore, belongs the distinction, in the history of invention, of having constructed the first reliable safety lamp.

What Is a Metal?

The oldest known metals in the world are gold and silver, copper, iron, tin and lead. They are to-day still the most useful and widely-used metals. Some of the properties by which we distinguish metals are the following: They are solid and not transparent; they have luster and are heavy. Mercury is an exception to the rule; it is a liquid, though yet a metal, and there is another, sodium, which is solid, though very light.

What Is the Most Valuable Metal?

If you were guessing you would naturally say that gold is, of course, the most valuable of the metals. But you would be wrong. The proper answer to this is iron. We do not mean the pound for pound value, for you could get much more for a pound of gold than for a pound of iron. We mean in useful value--iron is in that sense the most valuable metal known to man. This is true because iron is of such great service to man in so many ways, and it is very fortunate that there is such a great amount of it available for man's purposes. Iron is not generally found in a pure state in the mines. It is generally found compounded with carbon and other substances, and we obtain pure iron by burning these other substances out of the compound.

Iron is put upon the market in three forms, which differ very much in their properties. First, there is cast-iron. Iron in this form is hard, easily fusible and quite brittle, as you will know if you ever broke a lid on the kitchen range. In the form of cast-iron it cannot be forged or welded.

Next comes wrought-iron, which is quite soft, can be hammered out flat or drawn out in the form of a wire and can be welded, but fusible only at a high temperature. Third comes steel, the most wonderful thing we produce with iron. It is also malleable, which means that it is capable of being hammered out flat and can easily be welded, and this is the great property of steel--it acquires when tempered a very high degree of hardness, so that a sharp edge can be put on it, and when in that shape it will easily cut wrought-iron. Ordinarily we make wrought-iron and steel from iron that has been changed from its original state to cast-iron.

The term cast-iron is generally given to iron which has been melted and cast in any form desired for use. Stoves are made in this way. The iron is melted and then poured into a mold; while the product out of which wrought-iron and steel are made is technically cast-iron, the term pig-iron is used in speaking of iron which is cast for this purpose.

The process by which pig-iron is changed into wrought-iron is called _puddling_. The object of puddling, which is done in what is called a reverberatory furnace (which is a furnace that reflects or drives back the flame or heat) is to remove the carbon which is in the pig-iron. This is done partly by the action of the oxygen of the air at high temperature and partly by the action of the cinder formed by the burning furnace. When this has been done the iron is made into balls of a size convenient for handling. These are "shingled" by squeezing or hammering and passed between rolls by which the iron is made to assume any desired form.

Now we come to steel, the most wonderful product or form in which we take advantage of the value of iron. Steel was formerly made from wrought-iron, so that you first had to get cast-iron, from which you made wrought-iron, and eventually got steel by changing the wrought-iron. Now we make steel direct from pig-iron. This is known as the Bessemer process.

The most noticeable feature in the chemical composition of the different grades of iron and steel is found in the percentages of carbon they contain. Pig-iron contains the most carbon; steel the next lowest, and wrought-iron the least.

Iron has been known to men from early historical times. The smelting of iron ores is not any indication of advanced civilization either. Savage tribes in many parts of the world practiced the art of smelting, even before they could have learned it from people who had become civilized.

Why Is Gold Called Precious?

Gold is called one of the precious metals because of its beautiful color, its luster, and the fact that it does not rust or tarnish when exposed to the air. It is the most ductile (can be stretched out into the thinnest wire), and is also the most malleable (can be hammered out into the thinnest sheet). It can be hammered into leaves so thin that light will pass through them. Pure gold is so soft that it cannot be used in that form in making gold coins or in making jewelry. Other substances, generally copper, are added to it to make the gold coins and jewelry hard. Sometimes silver is also added to the gold with copper. The gold coins of the United States are made of nine parts of gold to one of copper. The coins of France are the same, while the coins of England are made of eleven parts of gold to one of copper. The gold used for jewels and watch-cases varies from eight or nine to eighteen carats fine.

Another reason why gold is called a precious metal is that it is very difficult to dissolve it. None of the acids alone will dissolve gold, and only two of them when mixed together will do so. These are nitric acid and hydrochloric acid. When these two acids are mixed and gold put into the mixture the gold will disappear.

What Do We Mean By 18-Carat Fine?

We often hear people in speaking of their watches say, “It is an 18-carat case.” Others speak of 14-carat watches or 22-carat or solid-gold rings.

When you see the marks on a watch-case or the inside of a gold ring they read 18 K or 14 K, or whatever number of carats the maker wishes to indicate. A piece of gold jewelry marked 18 K or 18 carats means that it is three-fourths pure gold. In arranging this basis of marking things made of gold, absolutely pure gold is called 24 carats. Then if two, six or ten twenty-fourths of alloy has been added, the amount of the alloy is deducted from twenty-four, and the result is either 22, 18 or 14 carats fine, and so on. On ordinary articles made by jewelers the amount of pure gold used is seldom over 18 carats, or three-fourths. Weddings rings (and these are considered solid gold) are generally made 22 carats fine, that is, there are only two twenty-fourth parts of alloy in them.

Why Does Silver Tarnish?

Silver is a remarkably white metal, which is associated with gold as one of the precious metals. It is harder than gold and will not rust, although it will tarnish, which gold will not, when exposed to certain kinds of air.

The silver tarnishes when it is exposed to any kind of air that has sulphur mixed in it. It ranks below gold as a precious metal for use in making ornaments and is not so costly, because there is a great deal more of it to be found in the world.

While silver is somewhat harder than gold, it is still not sufficiently hard to use pure for making coins, so, as in the case of the gold coins, it is mixed with something else--copper--to harden it. Otherwise our dimes and quarters would wear out too rapidly. Our silver coins are made of nine parts of silver to one of copper. The coins of France are in the same proportion, while the silver coins of England are made of 92½■ parts of silver to 7½■ parts of copper. German silver coins are made of three parts of silver and one of copper.

Why Do We Use Copper Telegraph Wires?

One of the characteristics which distinguishes copper is its color--a peculiar red. It stands next to gold and silver in ductility and malleability, and comes next to iron and steel in tenacity--which means the ability of its tiny particles to hang on to each other. That is why copper wire bends instead of breaking when you twist it. But that is not the only reason, although an important part of the reason, why we use copper for telegraph wires. Copper is an extremely good conductor of electricity when it is pure. So are gold and silver, but we cannot afford to buy gold and silver wires for the telegraph, telephone and other wires, and if we used such wires the cost of the equipment would be so great that we could not afford to have telephones in our homes. But there is a great deal of copper in the world and it is very cheap, and so it makes an ideal element for use in things through which electricity is to pass. When you compound it with other substances it loses some of its conductivity. Copper is used extensively in many ways in the world. This book is printed, for instance, from copper electrotype plates. The whole business of electrotyping is based on the use of copper.

Why Is Lead So Heavy?

Lead is a white metal and is noted for its softness and durability. It has a luster when freshly cut, but becomes dull quite soon after the freshly-cut surface is exposed to the air. Lead is the softest metal in general use. It can be cut with an ordinary knife. It can be rolled out into thin sheets, but cannot be drawn out into wire.

Lead is a very dense metal, that is, its particles are very compact and there is no room for air to circulate in between these particles. A piece of wood is lighter than a piece of lead of exactly equal bulk, because the little particles which make up the piece of wood are not very close together, and there is a lot of air in the ordinary piece of wood, while this is not true of the lead.

A great deal of lead is used in making pipes for plumbing. This is because lead pipe is comparatively cheap, although you might not think so when you think of the general conclusions we have been brought to form about plumbers and everything connected with them. Lead pipe is easily bent in any direction also, and is particularly good for use in plumbing for that reason.

Another wide use of lead is in making paints--white lead being the base used in making oil paints. The process of making white lead for paint is quite interesting and pictures of it are shown in “The Story In a Can of Paint” in another part of “The Book of Wonders.”

Why Are Cooking Utensils Made of Tin?

Tin is the least important of the six useful metals. It is also inferior in many ways to the others in this group of elements, but is tougher than lead and will make a better wire, though not a really good one. It has a whiteness and a luster that are not tarnished by ordinary temperature and is cheap. That is why it is used in making cooking utensils, pans, etc., and for roofs. But the pans, roofs, etc., are not pure tin. They are thin sheets of iron coated with tin. Pure tin would not be strong enough for these purposes, so a sheet of iron is first taken to supply the strength and then covered with tin to improve the appearance of the tin pans and keep them from rusting rapidly.

What Is Gravitation?

Gravitation is the result of the attraction which every body, no matter what its size, has for every other body. It is a strange force and difficult to explain in plain words. It is what keeps the heavenly bodies in their paths. Every one of the planets is held in its path by gravitation and every object on each of the planets is kept on the planet by gravitation. We can come nearer understanding gravitation by studying the effect of the attraction of gravitation on our own earth and the objects on it. When you throw a ball or a stone into the air it is the attraction of gravitation that causes it to come back. If this were not so the stone would go on up and up and would keep on going forever. If it were not for this wonderful force you could jump into the air and just keep on going up with nothing to bring you back. The reason you do not pull the earth toward you is because the body or mass with the greater bulk has always the greater pulling power.

This is a wonderful force. It cannot be produced nor can it be destroyed or lessened. It just is. It acts between all pairs of bodies. If other bodies come between any pair of bodies the attraction of gravity between the two outside bodies is neither lessened or increased, and yet each of the outside bodies will have an independent attraction or pull on the body which is in between.

No particle of time is spent by the transmission of the force of gravity from one body to another, no matter how far apart they may be. The only effect that distance has on the attraction of gravitation is to lessen its force. Any body which is being pulled through gravity toward another body would fall toward the center of the attracting body if all the force of attraction from all other bodies were removed.

What Is Specific Gravity?

Specific gravity is the ratio of weight of a given bulk of any substance to that of a standard substance. The substances taken as the standard for solids and liquids is water, and air or hydrogen for gases. Since the weights of different bodies are in proportion to their masses, it follows that the specific gravity of any body is the same as its density, and we now generally use the term “density” instead of specific gravity.

To find, for instance, the specific gravity of a given bulk of silver, we must take an equal bulk of water and weigh it. Then we also weigh the silver. We find that the silver weighs ten and a half times as much as the water, and so the specific gravity of silver is 10.5. If you will bear in mind that water is the standard used for measuring the specific gravity of solids and liquids, and that air or hydrogen are used as standards for the gases, you will always know what the figures after the words specific gravity mean.

Why Do We See Stars When Hit On the Eye?

We do not really see stars, of course, when we are hit on the eye or when we fall in such a way as to bump the front of our heads. What we do see, or think we see, is light.

To understand this we must go back to the explanation of the five senses--sight, hearing, feeling, tasting and touching. Now, each of these senses has a special set of nerves through which the sensations received by each of the senses is communicated to the brain and, as a rule, these special nerves receive no sensations excepting those which occur in their own particular field of usefulness. The eye then has nerves of vision; the nose, nerves of smell; the ear, nerves of hearing; the mouth, nerves of taste, and the entire body nerves of touch. As we have seen then, these special nerves are susceptible of receiving impressions or sensations only in their particular field. But, if you should be able to rouse the nerves of smell in an entirely artificial way and give them a sensation, they might easily act very much as though they smelled something. We find this often in the nerves of touch when we think we feel something when we do not.

Now, when some one hits you in the eye, the nerves of vision are disturbed in such a way as to produce upon the brain the sensation of seeing light. In other words, you cannot affect the eye nerves without causing the sensation of light, and that is just what happens when some one hits you in the eye.

The Story in a Submarine Boat

How Can a Ship Sail Under Water?

Up to a few years ago the stories we could tell about the ships that sail beneath the water were the creations of the minds of writers of fiction, like the author of “Twenty Thousand Leagues Under the Sea,” but to-day we can read of many actual trips beneath the water by the brave men who man our submarines. We never dreamed that the great story of Jules Verne would be realized in the little but very destructive ships of war which can be seen to-day in the naval ports of the nations of the world.

We might have had these submarines long ago but for the fact that the men who were trying to invent them would not give up the secrets which they had discovered. Many men in different parts of the world worked on this problem and each discovered one or more things which were valuable in working out a solution, and if they had all gotten together and compared notes between them they could have produced a submarine boat almost as good as those we have to-day.

How Does the Submarine Get Down Under the Surface?

The first essential in a vessel to enable it to navigate below the surface of the water is that it be made sufficiently strong to withstand the surrounding pressure of water, which increases at the rate of .43 of a pound for each foot of submergence.

A boat navigating at a depth of 100 feet would therefore have 43 pounds pressure per square inch of surface, or 6192 pounds for every square foot of surface. It will readily be seen, therefore, that the first essential is great strength. Therefore, the submarine boats are usually built circular in cross section with steel plating riveted to heavy framing, as that is the best form to resist external pressure. These boats are built for surface navigation as well, therefore they have a certain amount of buoyancy when navigating on the surface, the same as an ordinary surface vessel. When it is desired to submerge the vessel this buoyancy must be destroyed, so that the vessel will sink under the surface.

Now, the submerged displacement of a submarine vessel is its total volume, and, theoretically, a vessel may be put in equilibrium with the water which it displaces by admitting water ballast into compartments contained within the hull of the vessel, therefore, if a vessel whose total displacement submerged was 100 tons, the vessel and contents must weigh also 100 tons. If it weighed one ounce more than 100 tons it would sink to the bottom. If it weighed one ounce less than 100 tons it would float on the surface with a buoyancy of one ounce. If it weighed exactly 100 tons it would be in what submarine designers specify as being “in perfect equilibrium.”

It is possible to give a vessel a slight negative buoyancy to cause her to sink to, say, a depth of 50 feet and then pump out sufficient water to give her a perfect equilibrium, and thus cause her to remain at a fixed depth while at rest. In practice, however, this is seldom done. Most submarine boats navigate under the water with a positive buoyancy of from 200 to 1000 pounds and are either steered at the depth desired by a horizontal rudder placed in the stern of the vessel, or are held to the depth by hydroplanes, which hydroplanes correspond to the fins of a fish. They are flat, plane surfaces, extending out from either side of the vessel, and when the vessel has headway, if the forward ends of these planes are inclined downward, the resistance of the water acting upon the planes is sufficient to overcome the reserve of buoyancy and holds the vessel to the desired depth. If the vessel’s propeller is stopped, the boat, having positive buoyancy, will come to the surface.

By manipulating either the stern rudders or the hydroplanes, the vessel may be readily caused to either come nearer to the surface or go to a greater depth, as the change of angle will give a greater or less downpull to overcome the reserve of buoyancy.

The above description applies to navigating a vessel when between the surface of the water and the bottom.

Another type of vessel which is used for searching the bottom in locating wrecks, obtaining pearls, sponges, or shellfish, is provided with wheels. In this type of vessel the boat is given a slight negative buoyancy, sufficient to keep it on the bottom, and it is then propelled over the water bed on wheels, the same as an automobile is propelled about the streets. This type of vessel is also provided with a diver's compartment, which is a compartment with a door opening outward from the bottom. If the operators in the boat wish to inspect the bottom, they go into this compartment and turn compressed air into the compartment until the air pressure equals the water pressure outside of the boat; i. e., if they were submerged at a depth of 100 feet they would introduce an air pressure of 43 pounds per square inch into the diving compartment. The door could then be opened and no water could come into the compartment, as the diving compartment would be virtually a diving bell. Divers can then readily leave the boat by putting on a diving suit and stepping out upon the bottom.

[Illustration: ONE OF THE FIRST PRACTICAL SUBMARINES

"PROTECTOR." BUILT 1901-1902, BRIDGEPORT, CONN.

This was the pioneer Submarine Torpedo Boat of the level-keel type, and was built in Bridgeport in 1901-1902. It was shipped to St. Petersburg, Russia, during the Russian-Japanese war. From St. Petersburg it was shipped to Vladivostok, 6000 miles across Siberia, special cars being built for its transport.]

[Illustration: This picture illustrates the same vessel, also at full speed under engines, with the conning-tower entirely awash and with the sighting-hood and the Omniscope alone above water. Notwithstanding the limited areas exposed above the surface, still observation could be had well-nigh continuously either through the dead-lights in the sighting-hood or by means of the Omniscope.

In neither condition is it necessary to have recourse to electrical propulsion--the boats can still be safely and speedily driven as here shown under their engines.]

[Illustration: THE INSIDE OF A SUBMARINE

THE "G-1" RECENTLY DELIVERED TO THE UNITED STATES GOVERNMENT.

The largest, fastest submarine in the United States and the most powerfully armed submarine torpedo boat in the world.

In addition to the usual fixed torpedo tubes arranged in the bow of the vessel, which requires the vessel herself to be trained, the (seal) "G-1" carries four torpedo tubes on her deck which may be trained while the vessel is submerged, in the same manner as a deck gun on a surface vessel is trained, and thus fired to either broadside, which gives many technical advantages.]

[Illustration: The above view gives a general idea of the interior of a submarine torpedo boat and the method of operation when running entirely submerged with periscope only above the surface.

The commanding officer is at the periscope in the conning tower directing the course of the submarine through the periscope, which is a tube arranged with lenses and prisms which gives a view of the horizon and everything above the surface of the water, the same as if the observer in the submarine was himself above water. The steersman is shown just forward of the commanding officer and steers the vessel by compass under the direction of the commanding officer, the same as when navigating above the surface. In the larger type boats the steersman also has a periscope which enables him to see what is going on above the surface. Below decks two of the crew are shown loading a torpedo into the torpedo tube; each torpedo is charged with gun-cotton and will run under its own power over a mile and will explode on striking the enemy. The crew live in the compartment aft of the torpedo room. Aft of this is the engine room, in which are located powerful internal combustion engines for running on the surface and electric motors for running submerged. The electric motors are driven by storage batteries located under the living quarters. Wheels are shown housed in the keel, which may be lowered for navigating on the bottom in shallow water. A diving compartment in the bow permits divers to leave the vessel when on the bottom, to search for and cut or repair cables or to plant mines.]

[Illustration: A SUBMARINE SAILING CLOSE TO THE SURFACE

A submarine running partly submerged with the conning tower hatch open, showing the remarkable steadiness of this type of boat in a semi-submerged condition, a thing no other craft could safely accomplish.]

[Illustration: Another submarine running entirely submerged, periscope only showing. The flag is attached to top of periscope to show her position in maneuvers when periscope goes entirely under water.]

[Illustration: A PHOTOGRAPH TAKEN WITH THE PERISCOPE UNIVERSAL LENS.]

AN ALL-SEEING EYE FOR THE SUBMARINE

Vision under water is limited to but a few yards at best, and hence a submarine boat, when submerged, would be as blind as a ship in a dense fog and would have to grope its way along guided only by chart and compass, were it not for a device known as a periscope, that reaches upward and projects out of the water, enabling the steersman to view his surroundings from the surface. Of course the height of the periscope limits the depth at which the craft may be safely sailed. Nor can the periscope tube be extended indefinitely, because the submarine must be capable of diving under a vessel when occasion demands. But when operating just under the surface, where it can see without being seen, the craft is in far greater danger of collision than vessels on the surface, because it must depend upon its own alertness and agility to keep out of the way of other boats. The latter can hardly be expected to notice the inconspicuous periscope tube projecting from the water in time to turn their great bulks out of the danger course.

The foregoing article describes the type of periscope now in common use on submarines and one of the engravings on this page clearly illustrates the principles of the instrument. A serious defect of this type of instrument is that the field of vision is too limited. The man at the wheel is able to see under normal conditions only that which lies immediately before the boat. It is true that he can turn the periscope about so as to look in other directions, but this, of course, involves considerable inconvenience. On at least two occasions has a submarine boat been run down by a vessel coming up behind it.

[Illustration]

~SEEING IN ALL DIRECTIONS AT ONCE~

As long as the submarine has but a single eye it would seem quite essential to make this eye all-seeing; and since the two lamentable accidents just referred to, an inventor in England has devised a periscope which provides a view in all directions at the same time. This has been attempted before, but it has been found very difficult to obtain an annular lens mirror which would project the image down the periscope tube without distortion. The accompanying illustrations show how this difficulty has now been overcome. While we will not attempt to enter into a mathematical explanation of the precise form of the mirror lens, it will suffice to state that it is an annular prism. The prism is a zonal section of a sphere with a conoidal central opening and a slightly concave base. All the surfaces, however, are generated by arcs of circles owing to the mechanical inconvenience of producing truly hyperboloidal surfaces. The lens mirror is shown in section at _A_ in Fig. 1. The arrows indicate roughly the course of the rays into the lens and their reflection from the surface _B_, which is preferably silvered. The tube is provided with two objectives _C_ and _D_ (Fig. 3) between which a condenser _E_ is interposed at the image plane of the lens _C_. At the bottom of the periscope tube the rays are reflected by means of a prism _F_ into the eyepiece. Two eyepieces are employed. One of lower power, _G_, is a Kelner eyepiece, the purpose of which is to permit inspection of the whole image, while a high-powered eccentrically placed Huyghenian eyepiece, _H_, enables one to inspect portions of the image. The two eyepieces are mounted in a rectilinear chamber, _I_, which may be rotated about the prism at the end of the periscope, thus bringing one or other of the eyepieces into active position. The plan view, Fig. 4, shows in full lines the high-powered eyepiece in operative position, while the dotted lines indicate the parts moved about to bring the low-powered eyepiece into use. A small catch, _J_, shown in Fig. 2, serves to hold the chamber in either of these two positions. The high-powered eyepiece is mounted on a plate, _K_, which may be rotated to bring the eyepiece into position for inspecting any desired portions of the annular image. The parts are so arranged that when the eyepiece is in its uppermost position, as indicated by full lines in Fig. 2, the observer can see that which is directly in front of the submarine, and when the eyepiece is in its low position, as indicated by dotted lines, he sees objects to the rear of the submarine. With the eyepiece at the right or at the left he sees objects at the right or left, respectively, of the submarine. The high-powered eyepiece is slightly inclined, so that the image may be viewed normally and to equal advantage in all parts. Mounted above a plain unsilvered portion of the mirror is a scale of degrees which appears just outside of the annular image. A scale is also engraved on the plate _K_ with a fixed pointer on the chamber, making it possible to locate the position of any object and rotate the plate _K_ so as to bring the eyepiece _H_ on it. The scale also makes it possible to locate the object with respect to the boat.

[Illustration: HOW WE LOOK THROUGH A PERISCOPE

THE PERISCOPE TOP.]

[Illustration: PERISCOPE IN GENERAL USE.]

[Illustration: THE UNIVERSAL OBSERVATION LENS.]

This improved periscope is applicable not only to submarine boats but for other purposes as well, such as photographic land surface work, in which the entire surroundings may be recorded in a single photograph. The accompanying photograph, taken through a periscope of this type, shows the advantages of this arrangement and gives an idea of its value to the submarine observer when using the low-powered eyepiece. Of course, by using the other eyepiece any particular part of the view may be enlarged and examined in detail.

[Illustration: INSIDE OF A MINE-PLANTING SUBMARINE

MINE-PLANTING SUBMERSIBLE.

A Lake type vessel designed for planting contact mines. In naval warfare it is sometimes of advantage to plant mines, either to defend harbors, or in some cases the mines are planted in the course of the approaching enemy. This is a vessel designed for that purpose. The enemy is seen approaching, and the mine-planting submarine runs in ahead of them in a submerged condition and drops a number of contact mines on their course; the enemy strikes the mine and is blown up. A number of vessels were blown up by contact mines of this type in the Russian-Japanese war.]

Accidents and Their Causes.

The accidents which submarine vessels must guard against are as follows: collision, foundering, explosions and asphyxiation. The first danger is, however, no greater than those to which vessels that run entirely on the surface of the water are exposed. The eye of the submarine places the commander on a practical level with the commander of other vessels, so that if a collision occurs it is due to the same lack of watchfulness which causes collisions on the surface of the water.

The submarine boat is less liable to founder than an ordinary vessel, because she is built to withstand a greater pressure of water than other kinds of vessels. Of course, if a submarine springs a leak, she is in grave danger of sinking to the bottom, and there is less chance of the crew being rescued from a submarine, because no one but those on board know of the danger if the boat is under the water.

How Explosions May Occur.

In submarine vessels explosions may occur either through a collection of gases from the batteries or by reason of leaks in the pipes or tanks of the fuel supply system, or through the bursting of the air flasks belonging to the boat, or the air reservoirs in the automobile torpedoes. The greatest danger is from explosive gases and have been the cause of all explosions in modern submarine craft, and the greatest danger in this connection is the liability of a leak in the gasolene pipes or tanks. This gas is a heavy gas and so goes to the bottom of the vessel, where it is not so easily detected as a gas which rises. There is no certain way of guarding against leaks of gasolene. A leak may occur at any time in a pipe or tank of gasolene through some cause or other no matter how carefully inspected, and the gas from this is so active that it will go through the tiniest hole imaginable--even through a hole which water will not penetrate. The crew of a submarine is always subject to this danger unless the tanks are built outside the hull of the ship.

How the Air May Become Poisoned.

There is a constant danger of asphyxiation to the men in the submarine. A very small leakage of gas or the exhaust from an internal combustion engine may make the air so impure that those aboard will be overcome. A great deal of care must be taken to keep the air pure and to warn the crew at the first sign of danger from this.

When submarines first came into practical use, it was found a good idea to take a number of little white mice down with the vessel to warn all if the air began to become impure. As soon as this occurred, the mice became distressed and squealed as loudly as they could, thus warning those aboard the ship of danger. The mice felt the impurity of the air quicker than the men, not because they had any special gift to discover when the air was bad, but because they breathe much more quickly than man--take shorter and many more breaths.

Now, however, a chemical device has been invented which is affected in such a way as to ring a loud bell, if the air in the vessel becomes impure to such an extent that there is any danger.

Breathing the same air over and over may fill the vessel with carbonic acid gas. There should be no great danger from this, however, as submarines are now built sufficiently large to provide enough actually pure air for each man aboard for forty-eight hours, and it is hardly conceivable that a submarine need be submerged more than half that length of time under any conditions.

Of course, then, too, there is the danger of accident due to carelessness or ignorance. In other words, it is just as difficult to make a fool-proof submarine as a fool-proof anything else. Wherever anything is constantly dependent upon the continuous careful attention of human beings, there is constant danger of accident, whether it be on board a submarine, a railroad train, steamship or in connection with anything else.

[Illustration: A SUBMARINE UNDER THE ICE

UNDER-ICE SUBMARINE TORPEDO BOAT.

Submarine designed to navigate submerged under the ice, in ice-bound countries. Vessels of this type could enter harbors and destroy the enemy's shipping at will. A vessel of this type would also be of value in transporting mails, passengers and cargoes between ice-bound ports where navigation by surface vessels is closed for several months in the year.]

Story of How the Submarine Has Been Developed.

It is only within the past twenty years that man has been able to successfully navigate under the surface of the water.

~WHO MADE THE FIRST SUBMARINE BOAT?~

It has been a dream of inventors and engineers for the past three hundred years.

During the reign of King James I. a crude submarine vessel was built of wood, and was designed to be propelled by oars extending out through holes in the side of the vessel, the water being prevented from coming in through the openings by goat skins tied about the oars and nailed to the sides of the boat, which made a water-tight joint, but at the same time gave flexibility to the oars, so that by feathering them on the return stroke they could be manipulated to give head motion. Very little, if any, success could have attended this effort.

Nearly a hundred years later a man by the name of Day built a submarine and made a wager that he could descend to 100 yards and remain there 24 hours. He built a boat and submerged it in a place where there was a depth of 100 yards. He succeeded in remaining the 24 hours, and according to latest advices is still there, as he never returned to the surface.

There is very little information as to the construction of these early craft. The first really serious attempt at submarine navigation was made by a Connecticut man, a Dr. David Bushnell, who lived at Saybrook during the Revolutionary War. He built a small submarine vessel which he called the "American Turtle," and with it he expected to destroy the British fleet, anchored off New York during its occupation by General Washington and the Continental Army.

Thatcher's Military Journal gives a description of this vessel and describes an attempt to sink the British frigate "Eagle" of 64 guns by attaching a torpedo to the bottom of the ship by means of a screw manipulated from the interior of this submarine vessel.

A sergeant who operated the "Turtle" succeeded in getting under the British vessel, but the screw which was to hold the torpedo in place came in contact with an iron scrap, refused to enter, and the implement of destruction floated down stream, where its clockwork mechanism finally caused it to explode, throwing a column of water high in the air and creating consternation among the shipping in the harbor. Skippers were so badly frightened that they slipped their cables and went down to Sandy Hook. General Washington complimented Dr. Bushnell on having so nearly accomplished the destruction of the frigate.

If the performance of Bushnell's "Turtle" was such as described, it seems strange that our new government did not immediately take up his ideas and make an appropriation for further experiments in the same line. When the attack was made on the "Eagle," Dr. Bushnell's brother, who was to have manned the craft, was sick, and a sergeant who undertook the task was not sufficiently acquainted with the operation to succeed in attaching the torpedo to the bottom of the frigate. Had he succeeded the "Eagle" would undoubtedly have been destroyed and the event would have added the name of another "hero" to history and might then have changed the entire art of naval warfare. Instead of Bushnell being encouraged in his plans, however, they were bitterly opposed by

the naval authorities. His treatment was such as finally to compel him to leave the country, but he returned after some years of wandering, and under an assumed name, settled in Georgia, where he spent his remaining days practicing his profession.

Robert Fulton, the man whose genius made steam navigation a success, was the next to turn his attention to submarine boats, and submarine warfare by submerged mines. A large part of his life was devoted to the solution of this problem. He went to France with his project and interested Napoleon Bonaparte, who became his patron and who was the means of securing sufficient funds to build a boat which was called the “Nautilus.” With this vessel Fulton made numerous descents, and it is reported that he covered 500 yards in a submerged run of seven minutes.

~HOW SUBMARINES WERE DEVELOPED~

In the spring of 1801 he took the “Nautilus” to Brest, and experimented with her for some time. He and three companions descended in the harbor to a depth of 25 feet and remained one hour, but he found the hull would not stand the pressure of a greater depth. They were in total darkness during the whole time, but afterward he fitted his craft with a glass window 1½■ inches in diameter, through which he could see to count the minutes on his watch. He also discovered during his trials that the mariner’s compass pointed equally as true under water as above it. His experiments led him to believe that he could build a submarine vessel with which he could swim under the surface and destroy any man-of-war afloat. When he came before the French Admiralty, however, he was met with blunt refusal, one bluff old French admiral saying: “Thank God, France still fights her battles on the surface, not beneath it,” a sentiment which apparently has changed since those days, as France now has a large fleet of submarines. After several years of unsuccessful efforts in France to get his plans adopted, Fulton finally went over to England and interested William Pitt, then chancellor, in his schemes. He built a boat there, and succeeded in attaching a torpedo beneath a condemned brig provided for the purpose, blowing her up in the presence of an immense throng. Pitt induced Fulton to sell his boat to the English government and not bring it to the attention of any other nation, thus recognizing the fact that if this type of vessel should be made entirely successful, England would lose her supremacy as the “Mistress of the Seas.”

Fulton consented to do so, but would not pledge himself regarding his own country, stating that if his country should become engaged in war, no pledge could be given that would prevent him from offering his services in any way which would be for its benefit.

The English Government paid him $75,000 for this concession. Fulton then returned to New York and built the “Clermont” and other steamboats, but did not entirely give up his ideas of submarine navigation, and at the time of his death was at work on plans for a much larger boat.

Fulton had a true conception of the result of submarine warfare, and in a letter he says: “Gunpowder has within the last three hundred years totally changed the art of war, and all my reflections have led me to believe that this application of it will, in a few years, put a stop to maritime wars, give that liberty on the seas which has been long and anxiously desired by every good man, and secure to Americans that liberty of commerce, tranquillity, and independence which will enable citizens to apply their mental and corporeal facilities to useful and humane pursuits, to the improvement of our country and the happiness of the whole people.”

After Fulton’s death spasmodic attempts were made by various inventors looking to the solving of the difficult problem, but no very serious efforts were put forth until the period of the Civil War, and then a number of submarine boats were built by the Confederates. These boats were commonly called “Davids,” and it was one of them that sank the United States steamship “Housatonic” in Charleston Harbor on the night of the 17th of February, 1864. This submarine vessel drowned four different crews, a total of thirty men, during her brief career. At the time she sank the “Housatonic” her attack was anticipated, and sharp lookout was kept at all times; but, notwithstanding their vigilance, she succeeded in getting sufficiently close to plant a torpedo on the end of a spar, and sink this fine, new ship of 1400 tons displacement.

It will be seen from the above description that these vessels, while able to go under water, were not controllable.

After the Civil War several other inventors took up the problem of trying to design a submarine vessel that could be controlled as to maintenance of depth and direction under water.

In Europe, Gustave Zede, Goubet and Drzwiezki, and in this country Mr. Baker and Mr. John P. Holland, built experimental vessels.

In 1877 Mr. Holland built a small boat which was called the “Fenian Ram.” It is stated that this vessel was built with capital furnished by the “Clan-na-Gael,” with the idea of using it against the British fleet in an attempt to free Ireland.

While some slight success was met with by these inventors, it was not until about 1897 that any real progress was made.

~THE FIRST SUCCESSFUL SUBMARINE WITH HYDROPLANES~

In 1893, Simon Lake, an American inventor, submitted plans to the United States Naval authorities at Washington for a submarine boat that would navigate between the surface and the bottom by the use of what he called “hydroplanes,” which were designed to cause the vessel to submerge on an even keel. Mr. Lake’s design of vessel was also provided with wheels to enable it to navigate on the water bed. It was also provided with a diving compartment to enable the crew to don diving suits and leave the vessel, in working on wrecks, cutting cables, planting mines, etc.

In 1904 and 1905 he built a small vessel to demonstrate his principles and succeeded in successfully navigating the vessel on the bottom of New York Bay. He then built a larger vessel of about 50 tons displacement for further experimental purposes. This vessel was called the “Argonaut,” and was built in Baltimore in 1906 and 1907. This boat was successful from the start and covered thousands of miles in the Chesapeake Bay and along the Atlantic Coast, New York Bay and Long Island Sound, and was the first successful submarine boat to navigate in the open sea and on the water bed of the ocean.

Mr. Holland had, in 1894, received a contract for a submarine vessel for the United States Navy, and her construction was started in 1895. This vessel was called the “Plunger.” This was the first official recognition given to a submarine boat in the United States.

The Government of France had also given an order for a submarine boat which was under construction at this period.

The “Plunger” was never submerged, her construction covering a period of several years, and she was finally abandoned. Mr. Holland had, however, in the meantime prepared the designs of another vessel which he called “The Holland.” This vessel was accepted by the United States Government in 1900, and a number of other vessels of this type were built. These vessels were known as submarines of the diving type. They were controlled by means of a horizontal and vertical rudder placed at the stern of the vessel and the boat was, by means of these rudders, inclined down by the bow, and driven under the water by the force of their screw propeller.

England also built a number of submarines of the diving type.

In 1901 Mr. Lake brought out a larger vessel of his type, which was controlled by hydroplanes, which vessel was sold to the Russian Government, was shipped across the Atlantic to Kronstadt, and from there by rail to Vladivostok, and was in commission off Vladivostok just before the close of the Russian-Japanese War.

Mr. Lake then received orders from the Russian and other Governments for a number of additional boats of the even keel type, to be controlled by hydroplanes.

Mr. Lake’s principles of control have been now generally adopted by all Governments, as providing the safest and most reliable means of control of the vessel when navigating under the surface.

The United States Government has recently adopted this type to be built in their Navy Yards, and most other builders have adopted the hydroplanes as the means of maintaining depth when running beneath the surface.

[Illustration: CLEARING A CHANNEL OF BUOYANT MINES

This is one of the services to which submarine boats of this type lend themselves with peculiar fitness. It is possible for them to carry on this work with deliberation and to success, under the very guns and searchlights of a vigilant foe, without the slightest danger of being detected.

This would be accomplished preferably by the co-operation of two boats. They would take opposite sides in the channel, with a connecting rope extending out through the diving compartment. It is obvious that as they move along the rope will sweep the whole mine-field and gather in the connecting cables. This would be indicated at once to the operators in the diving compartment by the load upon the sweeping line. A grapple may then be attached to the rope and sent out of one boat and hauled into the other, and thus drag the mine so near that a diver could go out and destroy its electrical connections or cut it adrift. Should the latter operation be the aim, the grapple may be so fashioned as to accomplish this without the diver leaving the compartment. This latter method is one strongly recommended by some of the most prominent military authorities on submarine defense.]

[Illustration: This picture indicates the manner in which the boats have traveled many miles over all kinds of bottom. In the present instance the boat is shown systematically searching the bottom with her diving door open and strong lights being used to facilitate a more perfect examination.

There is no trim or equilibrium to maintain. When the propelling machinery stops the boat comes to rest. A cyclometer attached to these wheels gives a fairly reliable reading of the distance traveled under normal circumstances. As the currents do not carry her out of her course, and as her gauges give an absolute record of changing depths, it is possible to so navigate upon the bottom with remarkable precision. In shallow waters this method has many advantages.]

[Illustration: A MACHINE WHICH MAKES THE DIVER'S TASK EASY

SHOWING TUBE HANDLING CARGO IN SUNKEN SHIP.]

Recovering Cargo or Submerged Objects Without the Aid of Divers.

The operating tube is here shown within the body of a hulk and co-operating with the lifting derrick on the surface craft in the removal of the submerged cargo. A grab-dredge bucket of well-known construction is used, the jaws of which, when being lowered by one rope, open, and when strain is brought on the lifting rope, the jaws close. The working end of the tube is placed in the immediate neighborhood of the cargo to be lifted and, as the grab is being lowered from the boat above, the operator in the compartment controls the grab by means of the guide line shown attached to the small derrick boom, and leads it directly over the cargo to be lifted. The grab is then dropped and the signal sent to the vessel above to hoist. The moment the lifting line tautens the bucket grasps a load and fills itself with material in the manner common to this type of dredge. This method of directing intelligently and deliberately the dredge bucket may be applied as well to the removal of rock or any other obstruction or to any of those various services of kindred character familiar to submarine engineers. The great and prime advantage of the system is the fact that no divers are required, and the work is under the perfect control of an operator subject only to atmospheric pressure. In consequence, therefore, the only limit to the effective operating of this apparatus is the length of the tube, and, as has been said, this can be made long enough to reach depths denied to the diver simply by interposing additional sections.

LIVING QUARTERS ABOARD A SUBMARINE.]

Where Do Sponges Come From?

Until within comparatively recent years, the sponge was regarded as a plant; it is now known to belong to the animal kingdom, and to the order spongida of the class of rhizopoda. Sponge is an elastic, porous substance, formed of interlaced horny fibers, which produce by their numerous inosculations, a rude sort of network, with meshes or pores of unequal sizes, and usually of a square or angulated shape. Besides these pores there are some circular holes of large size scattered over the surface of most sponges, which lead into sinuous canals that permeate their interior in every direction. The oscula, canals, and pores, communicate freely together. The characteristic property of the sponge is the facility with which it absorbs a large quantity of any fluid, more especially of water, which is retained amid the meshes until forced out again by a sufficient degree of compression, when the sponge returns to its former bulk. From this peculiarity, combined with its pleasant softness, arises the value of the sponge for the purposes to which it is applied. In domestic economy and in surgical practice, there is no other product that can be satisfactorily substituted for it.

Sponge is an aquatic production, indigenous to almost every sea and shore. It is abundant and varied between the tropics, but becomes less so in temperate latitudes and continues to diminish in quantity, variety, and size, as it is traced into European and colder seas, until it almost disappears in the vicinity of the polar circles. Some sponges are known to be hermaphrodite, but that the individual at one period produces chiefly male elements, and later, chiefly female elements. Fertilization takes place in the body of the mother, and the egg here undergoes its early development. The embryo eventually bursts the maternal tissue and, passing into one of the canals, is caught by the current sweeping through the canal system and is discharged into the surrounding water through one of the large apertures on the surface of the sponge. In the Bahama Islands and along the coast of Florida, the breeding time of many sponges covers the period from mid-summer on through early Autumn.

There is propagation sometimes by ciliated gemmules, yellowish and oval, arising from the sarcode mass, and carried out by the currents. These are mostly formed in the spring, and after swimming freely about for a time, become fixed and grow. In its natural state, the sponge is a very different looking object from the article of commerce. The entire surface is covered with a thin, slimy skin, usually of a dark color, and perforated to correspond with the apertures of the canals. The sponge of commerce is in reality only the home or the skeleton of the sponge.

There are a few sponges that inhabit ponds and sluggish rivers; the others are marine. Of these, many of the calcareous and siliceous kinds inhabit the shores between tide-marks, preferring a site near the low ebb, where, nevertheless, they are daily alternately submerged, and left exposed to the atmosphere. The figured sponges with a fibrous texture, to whatever genus they belong, are denizens of deeper water, and are never left uncovered. They grow usually in groups, on rock shells, shellfish, corallines, and seaweeds, and either have no power of selection, or the quality of the site is indifferent to them.

How Do Sponges Grow?

In their growth, some sponges assume a determinate figure or at least one whose variations are confined within certain limits. The greater number are irregular and variable, their shape depending in a great measure upon the peculiarities of their state, to which they easily accommodate themselves. They will incrust a shell, or a crab, a rock, or seaweed, following every projection and sinuosity. The offshoots will spring up with a more luxuriant growth in the deeper sheltered places until the original shape of the foundation they grow upon is lost to sight.

Sponges are unmoving and inirritable. They never remain rooted to the places of the germination, and are incapable either of contracting or dilating themselves or even of moving any fiber or portion of their mass. The functions which distinguish them as living beings are few, and faintly imaged.

How Do Sponges Eat?

Although sponges lack the power of motion possessed by most animals, being nearly always attached, in one position or another, to some object, the study of their habits in captivity brings out many of their animal characteristics in a striking manner. Small specimens taken from the sea and placed in dishes of salt water may be kept alive for several hours if well cared for; and by using finely powdered coloring matter, such as carmine or indigo, the manner of their feeding may be readily observed. Sponges are more active in fresh sea water than in stale; they cannot be kept alive out of water and soon die if exposed to the air. Being unable to go in search of food, as a natural result, they can grow only in places where there is always an abundance of food suited to their wants. The great sponging grounds of the world are wholly confined within waters having a relatively high temperature during the entire year. The Old World sponges grow principally in the Mediterranean and the Red seas; the New World sponges are found about the Bahamas, southern and western Florida, and parts of the West Indies. The finest sponges come from the East, but one of the American species, the so-called “sheep’s wool,” stands high in favor.

The commercial sponges are separated into six species, three of which are European and three American. They are all referred to a single genus called spongia, and though having much in common as regards structure, their texture varies to such an extent as to make them of very unequal value for domestic purposes.

The Old World species may be arranged as follows, in order of their grade of excellence, beginning with the best quality: The Turkey cup sponge, Levant toilet sponge, the horse, honey comb, or bath sponge, and the Zimoca sponge. The American species include the sheep’s wool sponge, the yellow glove, violet, and grass, sponges. A very close relationship exists between the species of the two continents.

All known regions in which useful specimens abound contribute to the world’s supply. The trade is extensive. The demands upon the fisheries are great. In the Mediterranean, the fishing is carried on in some places at a depth of forty fathoms. Divers, naked, or in armor, go down to the bottom and tear off the sponges from their places of growth. In some places drag dredges are employed.

How Are Sponges Caught?

In the past quarter-century the sponge-fishery of the Florida coast has grown remarkably. Its headquarters is at Key West and several hundred sailing vessels are engaged in the industry. The fishing appliances consist of a small boat, a long hook, and a

waterglass. The hook is in reality a three-pronged spear attached to a pole thirty-five feet long. In searching for sponge the fishers row about in the small boat. By holding the glass on the surface of the water the bottom is plainly seen and small objects are readily discerned. When a sponge is sighted the pole with the hook attached is shot down and the product deftly gathered. The boat-load is brought to the deck of the schooner, allowed to remain there a few hours, and then is carried down into the hold. On Friday nights, the fishing generally ends for the week, and the vessel sails for some spot on the neighboring coast where there are established crawls, or places for curing the catch. These crawls are about 8 x 10 feet square, their purpose being to hold the sponges while maceration and decomposition take place. The resulting refuse is carried off by the tide.

The fishermen go away for another catch and the sponges are left in the crawls until the end of the following week when a new cargo is brought in. The returning fishermen beat the decomposed sponges with clubs, removing the impurities. The water is squeezed out, then the sponges are allowed to dry on the ground.

After drying, the hold of the large vessel is loaded to the utmost with the product and the voyage to Key West is made. Buyers from New York look over the sponges, and make offers for entire cargoes. The fishermen dispose of their goods rapidly and sail away for more. The buyers store the sponges in some dry building, and cause them to be bleached by lime. A popular manner of bleaching is to wash the sponges thoroughly in water, and then to immerse them in diluted hydrochloric acid to dissolve any of the calcareous substance. Having again been washed they are placed in another bath of dilute hydrochloric acid to which six per cent. of hyposulphite of soda, dissolved in a little warm water, has been added. In this bath the sponges remain for twenty-four hours, or until the bleaching process is completed. After bleaching, the sponges are pressed until their bulk is greatly reduced; they are then baled, and shipped to New York, which is the distributing point for the entire Florida product.

Sponges are by far the most important fishery products of Florida, representing about one-third of the annual value of the fishing industry. In 1899, the yield was over 350,000 pounds of sponges of which the first value was nearly $400,000.

Why Does Yeast Make Bread Rise?

There is a lot of sugar in the dough from which bread is made. Sugar contains three things--carbon, hydrogen and oxygen. When sugar is fermented it amounts practically to burning it. To make good bread from the dough it is necessary to ferment the sugar which is in the ingredients from which it is made. Yeast, which is a simple living plant, has the power to ferment sugar. When sugar ferments, two things are produced. One thing is the formation of carbonic acid gas. A great deal of this carbonic acid gas is caught in the dough in the form of large or small bubbles and some of it escapes into the air. The other part tries to escape into the air also but cannot, and causes the dough to rise, which makes the bread light, as we say. The holes you see in the bread after it is baked are the little pockets where the carbonic acid gas was retained in the dough. These bubbles of gas all through the dough act like a lot of little balloons and lift the dough up with themselves as they try to get to the top and escape into the air.

What Is Yeast?

Yeast is a living plant that is used for the purpose of causing fermentation. The yeast we use in baking bread is an artificial yeast--really a dough made of flour and a little common yeast and made into small cakes and dried. If kept free from moisture it retains the power of causing fermentation for some time. The flour and other matter in a cake of yeast are only used to keep the yeast in a form where it can be preserved. It is necessary to add water to start fermentation and that is why we add hot water when we stir in the yeast for a baking.

Is a Moth Attracted By a Light?

It seems to be a strange contradiction of the nature of living things that a moth should fly deliberately into a light or dash itself to death against the glass surrounding a strong light. This is contrary to the usual law of nature which gives the living thing an instinct to protect itself against enemies.

For a long time we thought that moths did not deliberately burn themselves up by flying right into a light, but our naturalists have proven that not only moths but certain birds, bees, flies and butterflies, burn themselves up by flying into the flame of a light or fire.

[Illustration: HOW MAN LEARNED TO MAKE A FIRE

SAWING

This was probably man’s first method of producing fire. By rubbing two sticks together in this way sufficient heat was produced to set fire to easily burnable material such as dried grass, etc.]

[Illustration: DRILLING

An improvement came when man learned that by twirling a dry stick in a hole in another piece of dry wood the fire could be started more quickly.]

How Man Discovered Fire

Fire was probably one of man’s first, if not the first, great discoveries, and has been one of his greatest servants as well as one of his greatest dangers. We do not know who discovered fire, or what nation first used it. It is, however, one of the signs that distinguishes man from the other animals. Not any of the lower animals was acquainted with the use of fire, while probably the earliest races of mankind seem to have been acquainted with it.

Mythology tells us wonderful stories of the origin of fire: according to these tales it was stolen from the sun, or the gods, and given to man; and Pandora, the first woman, was sent down to earth to punish man for his theft.

The most popular of these stories is the legend of Prometheus. According to this legend, fire, in the early days, was under the exclusive control of the gods. Prometheus, brother of Atlas, the god who supported the world on his shoulders, determined that the use of fire should be given to the people. He decided by some means to send a spark of fire to the earth, believing that one spark caught by man would start a burning flame that would never go out.

With this idea in mind, Prometheus visited Zeus, the great ruler, to carry out his purpose, for Zeus controlled fire. While Zeus was not looking, Prometheus “stole some brands of fire from the hearth, which he hid in the stalk of a fennel and sent it down to the earth.” Through this Prometheus gave to man his first knowledge of fire.

But while this story of fire may or may not be true, the use of fire rests entirely with man and his ingenuity. Through his ingenuity man was able to subject fire to his will; making it perform certain of his labors; and to a certain extent making it his servant; although it always did and always will get beyond his control at times.

Our ancestors were not satisfied with preserving the fire which the gods gave them; they tried and succeeded in producing it. One day one of them discovered that by rubbing two sticks together rapidly, the friction would create a fire. It was a most useful discovery. Before long the whole of mankind had learned this trick; others improved on this crude method until step by step men learned that by striking two pieces of flint or other hard mineral together, quicker action was obtained.

[Illustration: DRILLING WITH BOW STRING

Man’s ingenuity soon taught him that if he tied one end of a string to something and wrapped it around his drilling stick, one end of which was in a hole as in the first drilling picture, he could increase the rapidity of making fire.]

[Illustration: DRILLING WITH HELP

With some other to hold the drilling stick while he operated the string he was able to produce fire more quickly than he had ever done before.]

All kinds of methods were devised to increase knowledge of producing fire. The early Greeks found out how to catch the rays of the sun on a burning-glass and produce fire; the Romans achieved the same results through the use of mirrors.

[Illustration: PLOWING

This is another method man used for rubbing two pieces of wood together. In following this plan he usually used one stick of bamboo and rubbed it back and forth in a slot he had made in another piece of bamboo.]

[Illustration: FLINT AND PYRITES

In some places it was discovered that if you struck a piece of hard stone, like flint, against another, a spark was produced which could be caught on a bunch of dry grass or moss and so start a fire.]

In about A.D. 900, an Arab, named Bechel, discovered phosphorus, but it took almost 800 years more for Haukwitz to learn that when phosphorus was brought into friction with sulphur, fire would result. In another hundred years the world was benefited by the invention of the friction match--and since that time about one-half the people have been carrying matches about with them, able thus to start a fire easily any time.

~FIRE A MARK OF CIVILIZATION~

Fire and man's knowledge of it have had much to do with man's progress in civilization. Before man had fire, his life and movements were much like those of other animals. When man had learned to make a fire he was free to move and live anywhere and, therefore, people began to cover more territory.

[Illustration: THE FLINT AND STEEL METHOD OF MAKING FIRE

THE INTRODUCTION OF THE FLINT AND STEEL METHOD

Because fire was so important to him, man kept on trying to make this task easier. He finally contrived a tinder box when iron and steel became known. The tinder box is where he kept his flint and the piece of steel which he struck upon the flint. He also kept in the box pieces of cloth or paper on which he caught the sparks so produced.]

[Illustration: PISTOL TINDER BOX

This is a picture of a tinder box in the form of a pistol. It enabled man to produce sparks in greater numbers and more rapidly.]

[Illustration: PRODUCING SPARK WITH FLINT AND STEEL

This shows the method for striking the piece of steel against the flint to make the sparks fall on the cloth or paper in the box.]

[Illustration: A COMPLETE TINDER BOX SET

This picture shows a very complete tinder box set used by the wealthy people in the old days. A man carried this outfit with him just as today he carries matches.]

[Illustration: This tinder box set is very neat and compact. It is said still to be used among the Himalayan tribes where it was discovered.]

[Illustration: THE FIRST MATCHES

THE OXYMURIATE MATCH

This match, the first, was introduced in 1505. It was a slip of wood tipped with a chemical mixture. To light it it was necessary to stick its head into a bottle containing acid.]

[Illustration: PROMETHEAN MATCH

This was a paper cigarette dipped in a mixture of sugar and potash. Rolled within the paper was a tiny glass bulb filled with sulphuric acid. To light the match you pressed the bulb with pincers hard enough to break the bulb. This released the acid which set fire to the paper.]

What Would We Do Without Matches?

If one were to ask the man in the street what invention of the nineteenth century is his most constant and invaluable ally he might be mystified for the moment, but the undoubted answer would surely come in the single word "Matches." These familiar objects, apart from their luxurious use by smokers, are the indispensable servants of mankind from the moment of rising in the morning till the household is wrapped in sleep, and it is to them we turn when disturbed in the hours of darkness.

[Illustration: FIRST LUCIFER MATCH

Invented by John Walker in 1827. It consisted of a stick of wood tipped with sulphur and then with a chlorate mixture. To ignite it the match was drawn rapidly through a folded piece of sandpaper.]

[Illustration: MODERN SAFETY MATCH

The first practical match was made less than a century ago.]

No doubt “familiarity breeds contempt,” and it is difficult to imagine how man would fare, bereft of his box of matches. It might help the world to realize how much it owes to the inventors of the Lucifer Match, were it possible to cut off the supply of these magic fire producers for only one brief day. It requires no very vivid imagination to picture the consternation and confusion that such a step would produce, and there is a grim humor in wondering how the primitive methods of obtaining a light would serve the public convenience in these days of strenuous hustle.

Seeing that fire has been employed by man since prehistoric days, one would expect that easy means of obtaining it would have been devised in the early ages. We find, however, that until the beginning of the nineteenth century nothing in the nature of a match was available, and the crudest methods were still in use. We know from Virgil that in the reign of the Emperor Titus fire was obtained by rubbing decayed wood with a roll of sulphur between two stones, but it is not till Saxon times that we have evidence of the use of the tinder box with its flint and steel. That this latter was still regarded as something remarkable, as late as the fifteenth century, is proved by its representation in the collar of the Order of the Golden Fleece, which was founded in 1429. Burning glasses had, of course, been employed from the most primitive times, but one can imagine the despair of an early Briton who had to wait for a sunny day before he could boil his kettle.

Incredible as it may seem, it was not a time well within the memory of many people living to-day that matches in anything approaching the form now familiar were offered to the public. The way for their manufacture had been prepared by two discoveries; one by a German who isolated phosphorus in 1669; the other by a Frenchman who produced chlorate of potash in 1786. From this latter date the production of fire was much facilitated, and a few years before Queen Victoria came to the throne, John Walker--a chemist of Stockton-on-Tees--produced the first friction matches of which there is any certain record. These, called “Congreves,” were sold in boxes of fifty for 2/6, and their success soon led others to experiment in match manufacture, so that improvements were rapidly invented and factories sprang up in all parts of the country.

It would be a difficult task to compute accurately the value to the human race of the introduction to general use of this little article. At the present writing, in America the consumption of matches amounts to over a billion of matches a day.

How Matches Are Made.

To-day matches are in such demand that the ingenuity of man has devised a machine which makes complete matches without the help of the human hand.

At the very start of operations a man feeds blocks of wood into the jaws of the machine, and thenceforth the mechanical monster does its own work. Seizing the block from the man’s hand, the machine grips it between rollers and forces it against rows of keen-edged cutters, which are so arranged that there is little or no waste. Each of these cutters (and there are usually forty-eight in a machine) severs a piece of wood of exact size and shape. At the same moment a plate rises from beneath, which thrusts these little pieces of wood into a moving flexible cast-iron band, or rather into small holes in this band, from which the embryo matches project like bristles. This traveling band is about 700 feet in length, and follows a serpentine course in its journey, which occupies about an hour from start to finish, the speed being regulated according to temperature so that the matches may be quite dry when they reach the boxes.

When the band arrives at the finishing point, a steel bar punches out the matches stuck in its surface and they fall into the inside boxes placed ready to catch them. These boxes are kept continually shaking, to that no spaces are left and the matches fill them completely. As the inside boxes fill, a steel arm presses them forward into their covers, and they are passed along a trough in dozens, quickly wrapped in paper and sealed by a machine. Quick-fingered girls then wrap twelve of these dozen packages and we have the gross packages of boxes so familiar in the stores. It will be seen, that in spite of the marvellous machines which do so much, there is still plenty of work for human hands.

How Match Boxes Are Made.

The machines for making the wooden box which contain the matches are in themselves wonderful. First, a section of the trunk of an aspen tree, about 30 inches in length, is made to revolve in what is known as a peeling machine. After a few revolutions the rough outer surface is removed, and thin rolls of smooth-surfaced wood are peeled off or veneered. The machine at the same time scores the wood ready for folding by the boxmaking machine. Cut into skillets, i. e., into pieces of the size required for box covers or

insides, the ends are next dipped in pink dye to cover the edge of the wood which is not covered by the label. The skillets then go to the box machines, which fold and label them, and after half an hour in a cleverly devised drying chamber they are ready for use. In one room alone sixty machines are labelling and folding the skillets to the number of several thousand gross a day. To see these machines take a strip of wood, push it forward to receive the pasted label, fold it, fasten the joint, wipe off the superfluous paste, and, finally, toss the finished “outside” into a receiving basket, is as fascinating an example of mechanical ingenuity as the industrial world can afford.

Are Matches Poisonous?

A non-poisonous “strike anywhere” safety match, made from selected, clear, strong cork pine is now made in this country, and is the first satisfactory non-poisonous match. It is also the first match to be endorsed by the country’s recognized leaders and authorities in fire prevention and the conservation of human life and property.

The Hughes-Esch Anti-White Phosphorus Match Bill, which became a law during the administration of President Taft, was drafted by the attorneys of the American Association of Labor Legislation, and is the most drastic that our National Constitution will permit. It would be unconstitutional to absolutely prohibit the manufacture of white phosphorus matches, but the Hughes-Esch bill obtains the same result, viz.: absolute prohibition by means of excessive taxation. No match manufacturer in these days of keen competition can afford to pay a tax of ten cents on each box of white phosphorus matches made, and place his factory under government surveillance, for this tax of ten cents is over three times as much as his present selling price to the wholesale trade.

As soon as man learned to make fire and light, he began to appreciate how much more comfortable he could be if he could keep his lights burning and to have his light independent of his fire, because it was at times very uncomfortable to sit by a fire on a hot night simply because he wished to use the light which it made. The first schemes devised for lighting purposes merely were the camp-fire torch and the rushlight. With these as a basis, man was enabled to fashion more convenient forms of lighting. He invented the candle and the lamp, and grown “enlightened,” boxed his light in iron and in other metals.

Did Candles Come Before Lamps?

The candle is in appearance a primitive affair, yet there is little doubt that its predecessor was the lamp. Those old Egyptian tombs, which have unlocked many mysteries, held lamps, and through them evidence of ancient burial customs. Lamps played a part in the solemn feasts of the Egyptians, who on such occasions placed them before their houses, burning them throughout the night. Herodotus, in one of his numerous references to Xerxes, alludes to the hour of lamp-lighting, and evidences abound regarding the use of lamps among the ancient Greeks. Lamps, indeed, are pictured upon some of their oldest vases, indicating the symbolic significance which attached to them.

[Illustration: A French watch tower of the fifteenth century in time of siege. The tower is lighted by means of beacons and is protected by dogs. Ruins of such a tower can still be seen at Godesberger on the Rhine.]

What Were the Earliest Lamps?

It is probable that the earliest lamps were nothing more than convenient vessels, filled with oil and fired by means of rushes. Among the Romans pine splinters, the torch and the flambeau, supplied light until the fifth century before Christ, and even when the Roman began to use the lamp, it was by no means common, finding a place only in the homes of the rich, or on special festival days.

The custom of burning funeral lights beside the dead before interment is a very old one. Gregory, interpreting its significance for the Christian, says that departed souls, having walked here as the children of light, now walk with God in the light of the living. The Roman, Pliny, refers to the use of the pith of brittle rushes in making funeral lights and watch-candles, which were probably the ancient prototype of the old rushlight of England. Again, in speaking of flax, Pliny states that the part of the reed that is nearest to the outer skin is called tow, and is good for nothing but to make lamp-matches or candlewicks.

What Were the Lamps of the Wise and Foolish Maidens Made Of?

When lamps had come into general favor, better attention was given to their form and construction. The first seem to have been made of baked clay, moulded by hand into elongated vessels to contain the oil, and provided at one end with a lip to admit the wick.

These are the lamps which artists have pictured in the hands of the wise and foolish virgins, though in the opinion of some scholars they were merely rods of porcelain and iron, covered with cloth and steeped in oil. Another early type, which was less common, presents a simple disc with an aperture in the centre for the oil, and a hole for the wick, at one or both of the sides.

Under the Empire, when the light of the lamp had become general, the better ones were made of bronze, ornamented with heads, animals, and other decorations, attached to the handles, while as life in Rome partook more of luxury and extravagance, gold, silver, or Corinthian brass were the materials, the designs being more elaborate and complicated. Many and beautiful examples of these ancient lamps have been unearthed from the ruins of Herculaneum and Pompeii.

When Were Street Lamps First Used?

Dark must have been the lives of those people who, until comparatively recent times, lived, in the absence of sunlight, by the feeble, uncertain light of the primitive illuminants borne by these lamps. And as for street lighting--that was a luxury but seldom indulged in, and then, not for public benefit, but to enhance the glory of a potentate, or grace the obsequies of some great man. Even Rome, at the height of her luxury and beauty, rarely exhibited more than one or two lanterns in her streets. These were suspended over the baths and places of public resort. Occasionally, however, the streets were illuminated during festivals and other public occasions, while the Forum was sometimes lighted for a midnight exhibition. With these glittering exceptions, and that memorable one when, to satisfy the homicidal impulses of a bad emperor, the bodies of Christians were made living torches, Rome was a city of darkness.

[Illustration: THE FIRST STREET LIGHT IN AMERICA

The first street light in America. Early in 1795 several large cressets were placed on the corners of Boston’s most frequented street. Pine-knots were placed in these fire baskets by the night watchman.]

When Were Candles Introduced?

Historical records indicate the prevalent use of candles in the earliest days of Rome, but these candles were of the simplest sort--mere string or rope which had been smeared with pitch or wax. In the early Christian centuries it was the custom to dip rushes in pitch and coat them with wax, a method of candle-making that was long continued, for it was not until the fourteenth century that dipped tallow candles were introduced. In the Middle Ages wax candles provided the usual means of illumination, and these were made, not by common craftsmen, but by monks, or by the servants of the rich. Until the fifteenth century their use was confined to churches, monasteries and the houses of nobles, but the demand for them had become so great that the chandlers of London obtained an act of incorporation. As late as the eighteenth century the candles were made by dipping the wicks into melted wax or tallow, but about this time an ingenious Frenchman conceived the idea of casting them in metal moulds.

[Illustration: A part of the “Amende Honorable” of Jacques Coeur before Charles VII of France.]

[Illustration: A pagan votive lamp of bronze, now in the museum at Naples.]

It is only within a modern period that the state or city has assumed responsibility in the matter of public lighting, which for the most part had been left to the good will and public spirit of citizens. But in England a proclamation was issued to the effect that every individual should place a candle in each of the lower windows of his house, and keep it burning from nightfall until midnight.

[Illustration: THE FIRST OIL LANTERN

The first “Réverbère”--oil lantern--with a metal reflector, used to light the streets of Paris. It was invented by Bourgeois de Châteaublanc in 1765, and used until the introduction of gas.]

Paris was the first city to improve upon this method of street lighting, and in 1658 huge, vase-like contrivances, filled with resin and pitch, were set up in the principal thoroughfares. The improvement proving, as may readily be seen, both dangerous and expensive, the falct, so-called, were replaced by the lantern. This was at first simply a rude frame, covered with horn or leather, within which a candle burned. For more than one hundred years this was the extent of the illumination which the authorities could provide. But of course it was understood that no honest man would venture abroad without his torch or flambeau, and as London, Berlin, Vienna, and all leading cities of Europe, were in like case, the darkness of Paris could be borne.

[Illustration: Argand got his first suggestion for his burner--invented in 1780--from this style of alcohol lamp, then in general use throughout France.]

But progress had been made, and early in the eighteenth century the Corporation of London entered into contract with a certain individual to set up public lights, giving him permission to exact a sum of six shillings from every householder whose actual rent exceeded ten pounds. In the middle of the same century the Lord Mayor and Common Council applied to Parliament for power to light the streets of London better. From the granting of this permission dates improvement in public lighting.

Where Did the Word “Gas” Originate?

A Belgium chemist, Van Helmont, coined the word “gas” in the first half of the seventeenth century. The Dutch word “geest,” signifying “ghost,” suggested the term to him, and his superstitious neighbors hounded him into obscurity for talking of ghosts.

[Illustration: Hanging lamp from Nushagak in Southern Alaska. It is suspended from the framework of the tent by cords. Oils and fats from northern animals give a clear and steady light, and Eskimo lamps are frequently praised by travelers.]

[Illustration: WHAT THE BIG TANK NEAR THE GASWORKS IS FOR

SIX MILLION CUBIC FOOT GAS HOLDER.

Almost every boy and girl has seen the big tank near the gas works, and most of them have wondered what was in it and what it is for. This big tank is a “holder” in which the gas is stored after it is manufactured.

The giant holders are reservoirs from which gas is constantly being taken and the quantity on storage constantly replenished, as the ordinary gas plant never ceases manufacturing its product.

There is little or no danger of an interruption of the supply by reason of accident, as gas plants are always equipped with duplicate apparatus for emergencies.]

When Illuminating Gas Was Discovered.

The first practical demonstration of the value of gas made from coal for lighting was made by a Scotchman--Robert Murdock--who in 1797, after some years of experimenting, fitted up an apparatus in the workshop of Boulton and Watt, in Birmingham, England, which successfully lighted a portion of that establishment. The advantages of this kind of lighting were so apparent that its use was rapidly extended, although in many instances the people were afraid of it. For a time this kind of lighting was confined to street lights. One of the first great structures to be lighted by gas was Westminster Bridge in London, and great crowds gathered to watch the burning jets nightly. It was difficult to remove from the minds of the people the belief that the gas-pipes were filled with fire and the jets were only openings through which the flame in the pipes escaped. People sometimes touched the pipes expecting to find them hot, and when the pipes were put in buildings they made sure that they were placed several feet from the walls lest the fire in them set fire to the buildings.

The use of illuminating gas for lighting private houses developed quite slowly because of this fear of the fire in the gas-pipes. This was not entirely unwarranted, however, because at first the plumbers did not know, as they do now, how to prevent leakage of gas from the pipes. The methods of joining the pipes were oftentimes imperfect and, not realizing the dangers which would follow leaks, causing explosions, the workmen were often careless in installing the pipes.

The first American house in which gas was used for lighting was the home of David Mellville at Newport, R. I. Baltimore, Maryland, was the first American city to use gas for lighting. It was introduced there in 1817.

How Does Gas Get Into the Gas Jet?

If you hold a cool drinking glass over a burning gas jet for a moment, a film of moisture will form on the inside of the glass and remain until the tumbler becomes warm, and then disappear. Now, then, you will remember that water is a mixture of oxygen and hydrogen, and that when hydrogen is burned in the air, water is formed. It is also true that whenever water is formed by burning anything, hydrogen is present in it. You see, therefore, that the gas used for lighting purposes must contain hydrogen.

Let us now learn something more about what gas is made of. Wet a piece of glass with a little fresh lime water and hold this over the lighted gas jet. In a few moments a change takes place in the water. The water turns somewhat milky. This indicates the presence of carbonic acid gas, and the formation of carbonic acid gas, when burning is going on, means the presence of carbon.

From these two experiments we gather that the gas in the jet contains hydrogen and carbon. All kinds of illuminating gas contain these two substances. Sometimes there are small quantities of other substances present, but the value of gas for lighting depends on hydrogen and carbon.

We have already learned about hydrogen, but it would be well to re-learn about carbon.

Carbon is an element, and an extremely important one, for a large part of the composition of every living thing is carbon. It is found in more compounds than any other element. Almost pure carbon can easily be obtained by heating a piece of wood, in a covered utensil, until it is turned into charcoal. Charcoal, which is black, is composed almost entirely of carbon. It is a very interesting product in all ways; in connection with gas we are particularly interested in the fact that carbon will burn when heated in the air or in oxygen.

Charcoal is very much like hard coal, both being formed in practically the same way. Ages of years ago many large forests of trees were buried under a layer of soil and rocks, during changes that occurred in the earth's surface, and the hot inside earth slowly heated the wood, until almost nothing was left but the carbon.

[Illustration: WHERE THE GAS IS TAKEN FROM THE COAL

GENERATOR HOUSE AND 175-FT. STACK.

In the process of gas making, coal is placed in the generator and heated to an incandescent state, then from the top or bottom steam is admitted and forced through the heated coal, producing a crude water gas which is passed on to the carbureter. In this shell enriching oil is produced, but as the oil and the water gas do not effectually unite, they are passed on to the superheater, where, as its name implies, they are subjected to a high temperature which thoroughly gasifies them into a permanent gas.]

[Illustration: ILLUMINATING GAS MUST BE SCRUBBED

SHAVING SCRUBBERS.

After passing into the scrubbers the gas is cooled, passed into the scrubbers, and by contact with wooden slat trays, made up like screens; a large portion of the tar is removed from the gas, the tar passing off to large receptacles.]

Soft coal was formed in much the same manner, but the process was not so completely finished. Mixed with the carbon in soft coal we find quite a good deal of other substances, of which hydrogen forms the principal part. This is what makes soft coal valuable in the making of illuminating gas.

When soft coal is heated in a closed receptacle a gas is formed which will burn. To show this we have only to take an ordinary clay pipe, put a little piece of coal in the bowl, close the top with wet clay, and put the bowl part of the pipe in the fire. When it is quite hot, a gas will be found coming out of the stem of the pipe, which will, when lighted, burn.

The Story In a Gas Jet.

~HOW ILLUMINATING GAS IS MADE~

Soft coal is heated in large tubes of fire clay called retorts, and the gas that is formed is then collected in a large tank and sent through pipes to our homes after being purified. The part of the coal that is left consists largely of carbon and is what we call coke.

While the gas that comes directly from coal will burn if lighted, it is not a desirable gas to burn in our homes, because it contains a number of substances that should be eliminated before it is used for lighting.

How the Gas Is Purified.

From the clay retorts the gas passes through horizontal pipes containing water. This cools it and takes out of it most of the tar and water vapor that are driven off with the gas when formed. These substances settle in the water. The gas then goes through a series of curved pipes, which are air cooled. These pipes constitute what is known as an atmospheric condenser. From these the gas goes into a series of receptacles containing wooden slat trays, made up like screens. These receptacles are called the scrubbers, and they take out of the gas the last traces of tar and some of the other compounds found present. The removal of the sulphur is very important, for burning sulphur gives off a gas which is not only extremely impure to breathe, but also injurious to the health.

From the scrubbers the gas goes on through pipes to the purifiers--boxes which contain wood shavings coated with iron rust upon which the sulphur is deposited by chemical action. At the same time the lime absorbs a small quantity of carbonic acid gas, which is formed with the other gases. From the purifiers the gas passes into the great iron tanks, in which it is stored until needed.

The gas in the tanks consists chiefly of hydrogen, a number of compounds of hydrogen and carbon, and a small amount of a compound of carbon and oxygen containing less oxygen than carbonic acid gas, known as carbon monoxide. The hydrogen and carbon monoxide burn with a very pale flame, which gives but little light and much heat. The light-giving quality of the gas is found in the compounds of carbon and hydrogen. When these burn, the particles of carbon are heated white hot and glow very brightly, making a luminous flame.

There are, of course, some impurities in the purified gas. These are compounds containing sulphur and ammonia. The quantities of these substances, however, are so small that they are harmless; but the compounds taken out in the process of purifying the gas are saved, as considerable use is made of them. The water used for washing the gas is heavily charged with ammonia and is, in fact, the chief source of the ammonia sold by druggists.

[Illustration: HOW THE IMPURITIES ARE TAKEN FROM THE GAS

PURIFYING BOXES.

The principal impurity to be removed is sulphur, and this is accomplished by passing the gas through large iron rectangular boxes filled with wood shavings coated with iron rust upon which the sulphur is deposited by chemical action.]

[Illustration: STATION METER HOUSE, SHOWING CONSTRUCTION OF TWO NEW 13-FT. METERS.]

[Illustration: HOW THE METER MEASURES THE GAS

Fig 1

Fig 3

Fig. 2.

Fig 4

Gas first enters inlet pipe _A_ (Fig. 3) passing along _A1_ into covered valve chamber _B_ up through orifice _O_. It then passes down through two of the valve ports at the same time, ports _C_ and _D1_ (Fig. 2). Before _C1_ (Fig. 3) has gotten to its extreme opening, the valve on the opposite side has moved to allow gas to pass down port _D_. On every quarter turn of tangent _P_, one port is opening to receive gas which passes down through the valve ports into the chambers below (see arrows on Fig. 2), which shows the gas passing into chamber _F_. The pressure being greater on the outside of the diaphragm, forces the diaphragm inward and expels the gas from the inside of _D2_ through _D_ and passes over the cross-bar into the fork channel (see Fig. 1). On the other side gas is passing down through port _D1_ (Fig. 2) entering diaphragm _D3_, the pressure being greater on the inside of _D3_ therefore forces the diaphragm outward and expels the gas from the outside of diaphragm _D3_; out through port _C1_ into fork channel same as shown in (Fig. 1). All exhaust gas from the chambers below is checked from entering the chamber _B_ by the slide valve _G_ and _G1_ (Fig. 2). Instead of passing into chamber _B_ it passes over the cross-bars between _D1E1_ and _C1E1_ into the fork channels, then to outlet pipe _N_ (Fig. 3) to house pipe.

NOTE: All gas registered must pass through outlet _N_.]

In addition to coal gas made in the way just described, there is another form of illuminating gas, in the manufacture of which coal is indirectly employed. This gas, known as water gas, because it is formed by the decomposition of water, is produced by passing steam over red hot carbon, in the form of hard coal or coke. When this is done, the hydrogen in the steam is set free and the

oxygen combines chemically with the carbon, to form the carbon monoxide, that was mentioned as being present, in small proportions, in ordinary coal gas. This carbon monoxide is poisonous, if much of it is breathed, and as it has no odor it is difficult to detect when escaping. A number of deaths have resulted from water gas for this reason, and in some states the laws forbid its use for lighting purposes.

When water gas is used it must be enriched with some other substances before it will yield much light. You have already learned that neither hydrogen nor carbon monoxide burns with a bright flame, and you will see that water gas must have something added to it to fit it for lighting purposes. The substance usually added is the vapor of some light, volatile oil, like gasoline. This vapor is composed of compounds of carbon and hydrogen, and when it is mixed with the water gas it forms a gas that yields a very satisfactory light; and that may be produced more cheaply than common coal gas.

There remains one more form of illuminating gas which has been the subject of much discussion in recent years, namely, acetylene. This is a compound of carbon and hydrogen, in which there is twelve times as much carbon as hydrogen. It has not been discovered recently, for it was known early in the nineteenth century, but its possible use for lighting purposes was not considered then.

Attention was directed to it a few years ago by the discovery of a substance called calcium carbide. This is a compound of carbon and the metal calcium, formed by heating to a very high temperature a mixture of coal and lime. It has the peculiar property of decomposing, when treated with water. The calcium present combines with the oxygen and half the hydrogen of the water, to form common slacked lime or calcium hydrate, while the carbon and the remainder of the hydrogen combine to form acetylene gas.

The gas formed in this way needs no purifications before burning; it can be produced in small generators, and the production can be checked at any time. When burned in the proper form of burner it yields the brightest of all gas flames. For these reasons it is adapted for use in small villages and for lighting single houses. It is also frequently used in magic lanterns, where a strong and steady light is necessary. But the cost of producing acetylene in large quantities is greater than that of coal gas, and it seems extremely unlikely that it will ever be much used for lighting large cities and towns.

How the Light Gets Into the Electric Light Bulb.

The incandescent lamp was invented in 1879 and the patents were granted to Thomas A. Edison. There were, however, a number of electrical men who were working on the idea at this time who deserve a great deal of credit for developing the lamp.

The incandescent lamp, which is used chiefly for house lighting, consists of a glass bulb from which the air has been exhausted by pumps and chemical processes--in which there is a thin filament of tungsten metal wound on what is called an arbor (as shown in Fig. 4). This filament opposes high resistance to the passage of the current of electricity, and, consequently, is heated to incandescence when a current passes through it. The removal of the air from the bulb prevents the tungsten metal from burning up, as it would do if oxygen were present.

The filaments of the first lamps were made of vegetable fibre. The next development was the cellulose process, which is still used in carbon and metallized lamps, although a number of processes are used now which improve the filament considerably.

The discovery that tungsten metal could be used in incandescent lamps was made in 1906. The first tungsten lamp manufactured in America was made in 1907.

[Illustration: THE DEVELOPMENT OF INCANDESCENT LAMPS

Edison’s first lamp with a filament of bamboo fibre.]

[Illustration: The carbon lamp--the oldest form of incandescent lamp.]

[Illustration: Standard Mazda lamp--the highest development of the incandescent lamp.]

[Illustration: The Tantalum lamp developed just before the Mazda lamp.]

[Illustration: Improved Mazda lamp for lighting large areas--the most efficient lamp ever made.]

The filaments of the first tungsten lamps were composed of two or three short pieces of wire. In 1910, however, a lamp with a continuous tungsten filament was invented which increased the strength of the lamp wonderfully.

Mazda is a trade name given to all metal filament lamps made by the prominent American lamp manufacturers.

The reason that the Mazda lamp is so much more efficient than the carbon filament lamp is because the tungsten filament can be burned at a much higher temperature than the present carbon filament, without seriously blackening the bulb.

How Does an Arc Light Burn?

In the arc light a current of electricity is made to leap across from the tip of one rod of carbon to the tip of another that is held a short distance from the first. In passing across the current does not follow a straight path, but makes a curve, or arc, whence comes the name “arc light.”

In this form of light the carbons are not enclosed in a space from which air is excluded, consequently there is some destruction of the carbon. The light is due to the fact that the air between the tips of the carbon rods opposes a high degree of resistance to the current, so that the rods become intensely hot at their tips. The high degree of heat causes a slow burning of the carbon at the tips, and the small particles that burn are heated white hot before they are consumed, thus producing light.

In order to keep the light from an arc light uniform in strength, it is necessary to keep the tips of the carbon rods always the same distance apart. This is practically impossible, and, as a result, the arc light does not produce light that is well adapted for reading or for other purposes that require constant use of the eyes. The light produced by the arc light is very powerful, however, and for that reason it is much used for street lighting.

What Are X-Rays?

It was discovered by Professor Conrad Roentgen in 1895, that if a current of electricity be passed through a certain form of glass bulb, from which most of the air has been exhausted, a disturbance is produced in the ether that bears some resemblance to light waves. For want of a better name to give to a disturbance which was not well understood, Roentgen called his discovery the X-Ray, but it is now frequently called in his honor the Roentgen ray. The nature of this disturbance is not yet known, but as it does not affect the eye it is not light. These rays are produced with a glass vacuum tube and a battery from which a current of electricity is sent through the tube. The wires of the battery are connected with two electrodes, one of which consists of a concave disk of aluminum, and the latter of a flat disk of platinum. The X-rays are discharged in straight lines as shown in the figure. The most striking properties of the X-ray is its power to penetrate many substances that are impermeable to light. All vegetable substances, and the flesh of animals, are penetrated by it very readily. Glass, metals, bones, and mineral substances generally are opaque to it. Consequently, when a limb, or even the body of an animal, is exposed to X-rays they pass through the fleshy parts, but are stopped by the bones. Certain substances have the property of glowing, or becoming fluorescent, when exposed to the X-ray, and when screens of paper are coated with these substances they form a convenient means of detecting the presence of X-rays. By holding the hand between a tube that is giving off X-rays and a screen of this kind, the bones of the hand will be outlined in shadow on the screen, and the rest of the surface will glow with a greenish light. If a bullet or other piece of metal has become imbedded in the body, it may easily be located, if it is not in a bone, and the extent of an injury to a bone or a joint may be plainly shown. For this reason the X-ray is now widely used by surgeons.

How Man Learned to Fight Fire.

When you see the modern fire engine racing through the streets, gongs ringing, with the firemen hanging on and the police clearing the track, you should remember that it has taken man a long time to learn as much as he has about fighting fire.

No sooner did man learn to make fire than he found it necessary to learn how to put it out.

The first fire apparatus of record is found in Rome. The Gauls burned the city in 390 B. C., each citizen was ordered to keep in his house a “machine for extinguishing fire.” This consisted of a syringe.

The first record of an actual machine for putting out fire is by Hero of Alexandria. This contrivance, a “siphon used in conflagrations,” was used in Egypt about a hundred and fifty years before Christ.

The first record of what we would call a fire department is also found in Rome. A disastrous fire, occurring in the reign of Augustus called his attention to the benefit of a regular fire brigade would bring. So he organized a fire department. It consisted of seven

companies of a thousand men each.

The first real fire engines were used in 1633 at a big fire on London Bridge. The first fire hose was invented by the two Van der Heydes in 1672. One of the earliest engines used consisted of a tank drawn by two horses, which threw a stream an inch in diameter to a height of eighty feet. An improved engine was invented in 1721 by Newsham, of London, and the first engine used in the United States was made by Newsham. The first steam fire engine was invented by John Braithwaite, of London, in 1829.

Fire alarms came into use in medieval times. It was the custom, in many of the towns to have a watchman stationed on a high building whose duty it was to look for fires. As soon as he saw one, he gave warning by blowing a horn, firing a gun, or ringing a bell.

The first London fire department consisted of ten men of each ward.

The first municipal American fire department was created in Boston in 1678. The fire engine was a hand pump bought in England.

The first leather fire hose was made in America in 1808 in Philadelphia. Rubber hose was first made in England at about 1820.

How Did Man Learn to Cook His Food?

The primitive man lived on raw food--raw flesh, roots, fruits and nuts. There must have been a time when he lived thus because there was a time when he had no fires and no knowledge of how to make a fire. There are no records, however, to show when man learned that cooked food was best.

It must have come about almost simultaneously with his knowledge of fire, for the art of cooking goes back to the first knowledge of fire. We do not know either how man learned to make a fire. The earliest nations of which we have any record seem to have been acquainted with fire and certain methods for producing it. Not only one but all early nations seem to have been possessed of this knowledge. Occasionally travellers have reported that people have been found who were unacquainted with either fire or cooking, but investigation has always proven these reports unauthentic. Cookery has always been found in practice where people knew about fire.

It is strange how man has lost track of the beginning of his knowledge of fire and cookery, because fire represents the beginning of man’s culture and cookery goes hand in hand with it.

There are many legendary accounts of how man learned the value of cooked food, all of which are based upon the accidental burning or roasting of animals or birds. Perhaps, therefore, Charles Lamb’s “Roast Pig” story, which we read with much laughter in our school readers, was quite accurate from a historical standpoint. According to the story a man’s house burned and he cried more over the fate of his pet pig than about the loss of his house. He kept his pig in the house you will remember and as soon as the fire died away he rushed into the debris to look for his pet pig, hoping still to rescue him. He found him in a corner and made haste to pick him up and carry him into the open air. But the poor pig had been roasted to a turn and was still hot. The man’s fingers went right into the well done roast pig and were burned. With a cry he withdrew his fingers and put them into his mouth to blow on them and thus he secured his first taste of roast pig, which he found so much to his taste that he repeated the operation of licking his fingers.

While this is but a story, it is quite likely historically correct as to this discovery of the value of cooked food to some of the early nations. No doubt Fire and Cookery were developed together.

When man had learned to make fire, he found that it often got beyond his control. Here and there he would set the woods on fire quite without intention perhaps, but with damaging results. He would watch the conflagration and, when it was passed, he would find the baked bodies of deer or other animals which had been overcome by the fire and learned that baked meats were good to the taste and more easily digestible than raw meats.

Why Does a Sponge Hold Water?

A sponge will hold water because it has, on account of the plan on which it is grown the power of capillary attraction. The sponge is made up of little hair like tubes. If you take a glass tube, open at both ends and immerse one end in a vessel of water, you will find that the water will rise in the tube to a level higher than the surface of the water in the vessel. The smaller the hole through the glass

tube, the higher the water will rise. This is caused by the cohesion of the water against the inside surface of the hole in the tube and causes a pull upward. The water is pulled up into the tube because the surface of the tube has a greater cohesive attraction for the water than for the air which was in it and the air is forced out partly. Some liquids, such as mercury will not rise in the same way, but is depressed in a glass tube, since it cannot adhere to glass. Mercury however will run or rise in a tin tube, just as water in a glass tube, because it adheres to the tin.

Now a sponge is merely a lot of capillary tubes which have the same power of pulling up the water as the glass tube. The tubes in a sponge are so fine that the water will rise to the entire length of the tubes. In addition, this adhesive quality of water to the inside of the tubes in the sponge is so strong, that the sponge can be taken entirely out of the water and the water will remain in it.

Why Is the Right Hand Stronger Than the Left?

The right hand is stronger than the left only in case you are right-handed. If you have the habit of being left-handed, your left hand becomes stronger. If you are truly ambidextrous, your strength will be the same in both hands.

We get our strength by moving the various parts of the body, i. e., by using them. When a little baby stretches his arms and legs and kicks, he is only exercising naturally, making the blood circulate.

You can prove that the fact that your right hand is stronger than your left because of the greater use or exercise you give it, by tying your right arm close to your side and keeping it in that condition without using it for several weeks. When you remove the bands which held it tight, you will find your arm has lost its strength and that now your left hand is stronger. If, however, you are left-handed and tie that hand down for the same length of time, your right hand would be the stronger. This shows that the strength we have in our arms and legs, and other parts of the body, is developed by using them and giving them rational exercise. Of course, it is possible to over-use a part of the body, but you will notice that nature always gives us a warning by making us tired before we come to the point where further use of that particular part of the body would cause injury.

Why Do My Muscles Get Sore When I Play Ball In the Spring?

They do this because you have probably not been exercising the particular muscles which you employ in throwing a ball enough in the winter to keep you in good condition. Muscles which have been developed through use or work need more work to keep them in condition. In a sense certain of the muscles which you employ in playing ball have been treated during the winter very much as if you had tied them down, as we suggested you might do with your arm. You have not been using them--they have not been doing enough work, and they begin to lose their strength when for any period they have not been used enough. The soreness that you feel is the natural condition that arises when you begin to use a muscle that has been idle for some time.

Why Does a Barber’s Pole Have Stripes?

In early years the barber not only cut hair and shaved people, but he was also a surgeon. He was a surgeon to the extent that he bled people. In early times our knowledge of surgery was practically limited to blood letting. A great many of the ailments were attributed to too much blood in the body, and when anything got wrong with a man or woman, the first thing they thought of was to reduce the amount of blood in the body by taking some of it out.

The town barber was the man who did this for people and his pole represented the sign of his business.

The round ball at the top which was generally gilded represents the barbering end of the business. It stood for the brass basin which the barber used to prepare lather for shaving customers.

The pole itself represents the staff which people who were having blood taken out of their bodies held during the operation. The two spiral ribbons, one red and one white, which are painted spirally on the pole, represented the bandages. The white one stood for the bandage which was put on before the blood was taken out and the red one the bandage which was used for binding up the wound when the operation was completed.

How Was the Flag Made?

The design of our flag was outlined in a congressional resolution passed on June 14, 1777, which stated “that the flag of the thirteen United States be thirteen alternate stripes red and white; that the union be thirteen stars, white in a blue field, representing the new constellation.” After Vermont and Kentucky had been admitted to the Union, Congress made a decree in 1794 that after May 1, 1795, “the flag of the United States be fifteen stripes alternate red and white and that the Union be fifteen stars white on a blue field.” This made the stars and stripes again equal and it was the plan to add a new stripe and a new star for each new state admitted to the Union. Very soon, however, it was realized that the flag would be too large if we kept on adding one stripe for each new state admitted to the Union, so on April 4, 1818, Congress passed a resolution reducing the number of stripes to thirteen once more to represent the original colonies, and to add only a new star to the field when a new state was admitted to the Union. At this time there were twenty states in the Union. Since that time none of the flags of the United States have more than thirteen stripes while a new star has been added for each state until now we have forty-eight stars, representing the forty-eight states.

Why Are Some Guns Called Gatling Guns?

A gatling gun is a kind of gun invented by Richard Jordan Gatling in 1861 and 1862 and so it receives its name from its inventor. The original gatling gun had ten parallel barrels and was capable of firing 1,000 shots per minute when operated by hand power. It was discharged by turning a crank and would shoot in proportion to the rapidity with which the crank was turned. It was at first not a huge success but has from time to time been improved so that the crank is now turned by electric power and about fifteen hundred shots per minute can be fired with it.

How Did Hobson’s Choice Originate?

As used today, this expression means a choice with only one thing to choose. Tobias Hobson was a livery stable keeper at Cambridge, England, during the reign of King Charles I. He kept a stable of forty horses which he hired out by the hour or day, and was famous in his day so far as a livery stable keeper could be.

When you went to Hobson to hire a horse, you had the privilege of looking over all the horses in the stable to decide which one you would like to drive, but he always made you take the one in the stall nearest the door. In this way all the horses in the stable were worked in turn and while you might pretend to choose your own horse, you really had no choice--you had to take the one nearest the door or none. As soon as a horse was hired, the other horses in the stable were moved up, each one to the stall next towards the door so there was always a horse in the stall nearest the door.

Why Do They Call It a Honeymoon?

The word Honeymoon which is commonly used to describe the first few weeks after marriage, has always meant the first month or moon after marriage, but does not have any reference to the month or moon excepting as that describes a certain period of time.

The word originated in an old custom quite common among newly married couples among the ancient Teutons of drinking a kind of wine made from honey during the first thirty days after being married.

In these days newly married couples generally take a trip away from home for a short or longer period after their wedding day and this is called the honeymoon whether it is but a few days or three months or more. The custom of drinking wine made from honey has been abandoned so that the word is now used in an entirely different sense than formerly.

Why Is a Horseshoe Said to Bring Good Luck?

The luck of the horseshoe comes from three lucky things always connected with horseshoes. These consist of the following facts: It is the shape of a crescent; it is a portion of a horse; it is made of iron.

Each of these has from time immemorial been considered lucky. Anything in the shape of a crescent was always considered a thing to bring luck. From the earliest times, too, at least since the world knew something of the qualities of iron, iron has been regarded as a thing to give protection and incidentally that would involve good luck. And lastly the horse, since the days of English mythology, has been regarded as a luck animal. When, then, we had a combination of the three--the crescent, the iron and the horse in one object, it became a true lucky sign in the eyes of the people.

Some Wonders of the Human Body.

There are said to be more than two million little openings in the skins of our bodies to serve as outlets for an equal number of sweat glands. The body contains more than two hundred bones. It is said that as much blood as is in the entire body passes through the heart every minute, i.e., all the blood in the body goes in and out of the heart once every minute. The lung capacity of the average person is about 325 cubic inches.

With every breath you inhale about two-thirds of a pint of fresh air and exhale an equal amount if you breathe normally.

The stomach of the average adult person has a capacity of about five pints and manufactures about nine pounds of gastric juice daily.

There are over five hundred muscles in the body all of which should be exercised daily to keep you in the best condition. The average adult human heart weighs from eight to twelve ounces and it beats about 100,000 times every twenty-four hours. The perspiration system in the body has only very small ducts or pipes, but there are about nine miles of them. The average person takes about one ton of food and drink each year. We breathe about eighteen times a minute, which amounts to about 3,000 cubic feet an hour.

Where Did the Expression “Kick the Bucket” Originate?

The expression originally came from the method used in stringing a hog after killing it. The pig after being slaughtered was hung by the hind legs. A piece of bent wood was passed in behind the tendons of each of the hind legs and the pig hung up by this stick of wood much like we hang up clothes with a clothes hanger today. The piece of wood was called a bucket. The “bucket” part of the expression does not, therefore, refer to a bucket at all but to this bent piece of wood. All are not agreed on this explanation, however, as it does not explain where the “kick” comes in. Many investigators hold to the belief that a man named Bolsover was the first to “kick the bucket” literally and that the expression came from the manner of his death. He stood on a pail or bucket while arranging to hang himself by tying a rope around his neck and to a beam which he could not reach without standing on the bucket. When ready he kicked the bucket out from under his feet and so succeeded in carrying out his own wishes and in so doing coined a famous expression which still means “to die.”

How Did the Word “News” Originate?

The word “News” which was created to describe what newspapers are supposed to print, came from the four letters which have for ages been used as abbreviations of the directions of the compass. In this N stands for North, E for East, S for South and W for West, and in illustrating the points of the compass the following diagram has long been used:

N | W--+--E | S

The earliest newspapers always printed this sign on the front pages of their papers in every issue. This was done to indicate that the paper printed all the happenings from four quarters of the globe.

Later on some enterprising newspaper man who may have forgotten the original significance of the letter in the diagram, arranged the letters N. E. W. S. in a straight line at the head of the paper and that is how what we read in the papers came to be known as news.

Almost one-half the whole number of newspapers published in the world are published in the United States and Canada.

Who Made the First Umbrella?

No one knows who made the first umbrella but we know that Jonas Hanway of London was the first man to carry one over his head to keep off the rain.

Umbrellas seem to have been known as far back as the days of Ninevah and Persepolis, for representations of them appear frequently in the sculptures of those early days. The women of ancient Rome and Greece carried them but the men never did.

Mr. Hanway is said to be the first man who walked in the streets of London with an open umbrella over his head to keep off the rain. He is said to have used it for thirty years before they came into general use for this purpose.

[Illustration: HOW MAN LEARNED TO TELL TIME

The first picture shows what was probably man's first method of telling time. The principle was the same as that of the sun-dial. It provides to-day an accurate method of telling time.

Of course, man in the early days needed to find some other means of noting the passing of time at night, for then the sun cast no shadow for him. His ingenuity taught him to make a candle which was light and dark in alternate rings, and as each section burned he made a mark to record the passing of a certain length of time. Before candles were invented he used a rope in which he tied knots at equal spaces apart and which he burned as shown in the third picture.]

The Story in a Time Piece

What Is Time?

Time, as a separate entity, has not yet been defined in language. Definitions will be found to be merely explanations of the sense in which we use the word in matters of practical life. No human being can tell how long a minute is; only that it is longer than a second and shorter than an hour. In some sense we can think of a longer or shorter period of time, but this is merely comparative. The difference between 50 and 75 steps a minute in marching is clear to us, but note that we introduce motion and space before we can get a conception of time as a succession of events, but time, in itself, remains elusive.

In time measures we strive for a uniform motion of something and this implies equal spaces in equal times; so we here assume just what we cannot explain, for space is as difficult to define as time. Time cannot be "squared" or used as a multiplier or divisor. Only numbers can be so used; so when we speak of "the square of the time" we mean some number which we have arbitrarily assumed to represent it. This becomes plain when we state that in calculations relating to pendulums, for example, we may use seconds and inches--minutes and feet--or seconds and meters--and the answer will come out right in the units which we have assumed. Still more, numbers themselves have no meaning till they are applied to something, and here we are applying them to time, space and motion; so we are trying to explain three abstractions by a fourth! But, happily, the results of these assumptions and calculations are borne out in practical human life, and we are not compelled to settle the deep question as to whether fundamental knowledge is possible to the human mind.

What Was Man's First Division of Time?

Evidently, man began by considering the day as a unit and did not include the night in his time-keeping for a long period. "And the evening and the morning were the first day," Gen. i, 5; "Evening and morning and at noonday," Ps. lv, 17, divides the day ("sun up") in two parts. "Fourth part of a day," Neh. ix, 3, shows another advance. Then comes, "are there not twelve hours in a day," John xi, 9. The "eleventh hour," Matt. xx, 1 to 12, shows clearly that sunset was 12 o'clock. A most remarkable feature of this 12-hour day, in the New Testament, is that the writers generally speak of the third, sixth and ninth hours, Acts ii, 15; iii, 1; x, 9. This is extremely interesting, as it shows that the writers still thought in quarter days (Neh. ix, 3) and had not yet acquired the 12-hour conception given to them by the Romans. They thought in quarter days even when using the 12-hour numerals! Note, further, that references are to "hours"; so it is evident that in New Testament times they did not need smaller subdivisions. "About the third hour" shows the mental attitude. That they had no conception of our minutes, seconds and fifth-seconds becomes quite plain when we notice that they jumped down from the hour to nowhere, in such expressions as "in an instant--in the twinkling of an eye."

Before this the night had been divided into three watches (Judges vii, 19). Poetry to this day uses the "hours" and the "watches" as symbols.

This twelve hours of daylight gave very variable hours in latitudes some distance from the equator, being long in summer and short in winter. The amount of human ingenuity expended on time measures so as to divide the time from sunrise to sunset into twelve equal parts is almost beyond belief. In Constantinople, to-day, this is used, but in a rather imperfect manner, for the clocks are modern and run twenty-four hours uniformly; so the best they can do is to set them to mark twelve at sunset. This necessitates setting to the varying length of the days, so that the clocks appear to be sometimes more and sometimes less than six hours ahead of ours. A clock on the tower at the Sultan's private mosque gives the impression of being out of order and about six hours ahead,

but it is running correctly to their system. Hotels in Constantinople often show two clocks, one of them to our twelve o'clock noon system. Evidently the Jewish method of ending a day at sunset is the same and explains the command, "let not the sun go down upon thy wrath," which we might read, "do not carry your anger over to another day."

This simple line of steps in dividing the day and night is taken principally from the Bible because every one can easily look up the passages quoted and many more, while quotations from books not in general use would not be so clear.

How Did Man Begin to Measure Time?

Now, as to the methods of measuring time, we must use circumstantial evidence for the prehistoric period. The rising and the going down of the sun--the lengthening shadows, etc., must come first, and we are on safe ground here, for savages still use primitive methods like setting up a stick and marking its shadow so that a party trailing behind can estimate the distance the leaders are ahead by the changed position of the shadow. Men notice their shortening and lengthening shadows to this day. When the shadow of a man shortens more and more slowly till it appears to be fixed, the observer knows it is noon, and when it shows the least observable lengthening then it is just past noon. Now, it is a remarkable fact that this crude method of determining noon is just the same as "taking the sun" to determine noon at sea. Noon is the time at which the sun reaches his highest point on any given day.

[Illustration: The Sun-dial is only an improvement on the stick which cast a shadow which enabled man to tell the time of day at any hour. The shadow moves around the dial, falling on the numbers on the circle.]

How Is the Time Calculated at Sea?

At sea this is determined generally by a sextant, which simply measures the angle between the horizon and the sun. The instrument is applied a little before noon and the observer sees the sun creeping upward slower and slower till a little tremor or hesitation appears, indicating that the sun has reached his height--noon. Oh! you wish to know if the observer is likely to make a mistake? Yes, and when accurate local time is important, several officers on a large ship will take the meridian passage at the same time and average their readings, so as to reduce the "personal error." All of which is merely a greater degree of accuracy than that of the man who observes his shadow.

The gradual development of the primitive shadow methods culminated in the modern sun-dial. The "dial of Ahas" (Isa. xxxviii, 8), on which the sun went back ten "degrees," is often referred to, but in one of the revised editions of the Bible the sun went back ten "steps." This becomes extremely interesting when we find that in India there still remains an immense dial built with steps instead of hour lines.

In a restored flower garden, within one of the large houses in the ruins of Pompeii, may be seen a sun-dial of the Armillary type, presumably in its original position. It looks as if the plane of the equator and the position of the earth's axis must have been known to the maker.

Both these dials were in use before the beginning of our era and were covered by the great eruption of Vesuvius in 79 A.D., which destroyed Pompeii and Herculaneum.

~THREE GREAT STEPS IN MEASURING TIME~

Modern sun-dials differ only in being more accurately made and a few "curiosity" dials added. The necessity for time during the night, as man's life became a little more complicated, necessitated the invention of time machines. The "clepsydra," or water-clock, was probably the first. A French writer has dug up some old records putting it back to Hoang-ti 2679 B.C., but it appears to have been certainly in use in China in 1100 B.C., so we will be satisfied with that date. In presenting a subject to the young student it is sometimes advisable to use round numbers to give a simple comprehension and then leave him to find the overlapping of dates and methods as he advances. Keeping this in mind, the following table may be used to give an elementary hint of the three great steps in time measuring.

Shadow time, 2000 to 1000 B.C.

Dials and water-clocks, 1000 B.C. to 1000 A.D.

Clocks and watches, 1000 to 2000 A.D.

Gear-wheel clocks and watches have here been pushed forward to 2000 A.D., as they may last to that time, but no doubt we will supersede them. At the present time science is just about ready to say that a time measurer consisting of wheels and pinions--a driving power and a regulator in the form of a pendulum or balance, is a clumsy contrivance and that we ought to do better very soon.

It is remarkable how few are aware that the simplest form of sun-dial is the best, and that, as a regulator of our present clocks, it is good within one or two minutes. No one need be without a “noon-mark” sun-dial; that is, every one may have the best of all dials. Take a post or any straight object standing “plumb,” or best of all the corner of a building. In the case of the post, or tree trunk, a stone (shown in solid black) may be set in the ground; but for the building a line may often be cut across a flagstone of the footpath. Many methods may be employed to get this noon mark, which is simply a north and south line: Viewing the pole star, using a compass (if the local variation is known) or the old method of finding the time at which the shadow of a pole is shortest. But the best practical way in this day is to use a watch set to local time and make the mark at 12 o’clock.

[Illustration:

Drawing by James Arthur.

A form of Sun-dial that is as good to-day as any dial for determining noon.]

On four days of the year the sun is right and your mark may be set at 12 on these days, but you may use an almanac and look in the column marked “mean time at noon” or “sun on meridian.” For example, suppose on the bright day when you are ready to place your noon mark you read in this column 11.50, then when your watch shows 11.50 make your noon mark to the shadow and it will be right for all time to come. Owing to the fact that there are not an even number of days in a year, it follows that on any given yearly date at noon the earth is not at the same place in its elliptical orbit, and the correction of this by the leap years causes the equation table to vary in periods of four years. The centennial leap years cause another variation of 400 years, etc., but these variations are less than the error in reading a dial.

How Did Men Tell Time When the Sun Cast No Shadows?

WATER CLOCKS FOR TELLING TIME

This picture shows the hour-glass or sand-glass. It is really a type of water-clock, being based on the same principle. The upper glass bulb was filled with sand and this sand fell through a little hole between the two bulbs. When the sand had all gone through, the glass was turned upside down and the operation repeated.

TIME-BOY OF INDIA.--WATER-CLOCK.

The Water-clock consisted of a large vessel filled with water, on the surface of which was placed a smaller vessel, really a gong, with a hole in the bottom. The water gradually filled the smaller vessel, and it sank. The Time-boy sat beside the Water-clock and as soon as the vessel sank he fished it out, emptied it, struck the gong one or more times and set it on the water again.]

During the night and also in cloudy weather the sun-dial was useless, and we read that the priests of the temples and monks of more modern times “went out to observe the stars” to make a guess at the time of night. The most prominent type after the shadow devices was the “water-clock” or “clepsydra,” but many other methods were used, such as candles, oil lamps, and in comparatively late times, the sand-glass. The fundamental principle of all water-clocks is the escape of water from a vessel through a small hole. It is evident that such a vessel would empty itself each time it is filled in very nearly the same time. The reverse of this has been used, as shown in the picture of the Time-boy of India. He sat in front of a large vessel of water and floated a bronze cup having a small hole in its bottom in this large vessel, and as the water ran in through the hole the cup sank. The boy then fished it up and struck one or more blows on it as a gong. This he continued and a rude division of time was obtained--while the boy kept awake!

[Illustration: Drawing from description by James Arthur.

The “Hon-woo-et-low,” Canton, China. Copper jars dropping water.]

The most interesting of all water-clocks was undoubtedly the “copper jars dropping water,” in Canton, China, where it can still be seen. Referring to the picture herewith and reading the four Chinese characters downwards the translation is “Canton City.” To the left and still downwards, “Hon-woo-et-low,” which is, “Copper jars dropping water.” Educated Chinamen inform me that it is over 3000 years old. The little open building or tower in which it stands is higher than surrounding buildings. It is, therefore, reasonably safe to state that the Chinese had a weather and time station over 1000 years before our era.

[Illustration:

Photo by James Arthur.

TOWER OF THE WINDS.

This tower is located at Athens, Greece. It was built about 50 B.C. It is octagonal in shape and had at one time sun-dials on each of its eight sides. On top was a bronze weather vane from which it derived its name.]

~A PRIMITIVE TWELVE-HOUR CLOCK~

It is a 12-hour clock, consisting of four copper jars partially built in masonry forming a stair-like structure. Commencing at the top jar each one drops into the next downward until the water reaches the solid bottom jar. In this lowest one a float, “the bamboo stick,” is placed and indicates the height of the water, and thus in a rude way gives the time. It is said to be set morning and evening by dipping the water from jar 4 to jar 1, so it runs 12 hours of our time. What are the uses of jars 2 and 3, since the water simply enters them and drips out again? No information could be obtained, but I venture an explanation and hope the reader can do better, as we are all of a family and there is no jealousy. When the top jar is filled for a 12-hour run it would drip out too fast during the first six hours and too slow during the second six hours, on account of the varying “head” of water. Now, the spigot of jar 2 could be set so that it would gain water during the first six hours, and lose during the second six hours, and thus equalize a little by splitting the error of jar 1 in two parts. Similarly, these two errors of jar 2 could be again split by jar 3 making four small variations in lowest jar, instead of one large error in the flow of jar 1. This could be extended to a greater number of jars, another jar making eight smaller errors.

The best thing the young student could do at this point would be to grasp the remarkable fact that the clock is not an old machine, since is covers only the comparatively short period from 1364 to the present day. Compared with the period of man’s history and inventions it is of yesterday. Strictly speaking, as we use the word clock, its age from De Vick to the modern astronomical is only about 540 years. If we take the year 1660, we find that it represents the center of modern improvements in clocks, a few years before and after that date includes the pendulum, the anchor and dead beat escapements, the minute and second hands, the circular balance and the hair spring, along with minor improvements. Since the end of that period, which we may make 1700, no fundamental invention has been added to clocks and watches. This becomes impressive when we remember that the last 200 years have produced more inventions than all previous known history--but only minor improvements in clocks! The application of electricity for winding, driving, or regulating clocks is not fundamental, for the time-keeping is done by the master clock with its pendulum and wheels, just as by any grandfather’s clock 200 years old. This broad survey of time measuring does not permit us to go into minute mechanical details.

[Illustration: THE FIRST MODERN CLOCK

Drawing by James Arthur.

Modern clocks commence with De Vick’s of 1364, which is the first unquestioned clock consisting of toothed wheels and containing the fundamental features of our present clocks. References are often quoted back to about 1000 A.D., but the words translated “clocks” were used for bells and dials at that date; so we are forced to consider the De Vick clock as the first till more evidence is obtained. It has been pointed out, however, that this clock could hardly have been invented all at once; and therefore it is probable that many inventions leading up to it have been lost to history. That part of a clock which does the ticking is called the “escapement,” and the oldest form known is the “Verge.”]

~EARLIEST CLOCKS HAD NO DIALS OR HANDS~

Scattered references in old writings make it reasonably certain that from about 1000 A.D. to 1300 A.D. bells were struck by machines regulated with this verge escapement, thus showing that the striking part of a clock is older than the clock itself. It seems strange to us to say that many of the earlier clocks were strikers only, and had no dials or hands, just as if you turned the face of

your clock to the wall and depended on the striking for the time.

[Illustration:

Photo by James Arthur.

ENGLISH BLACKSMITH'S CLOCK.]

A good idea of the old church clocks may be obtained from the picture herewith. Tradition has followed it down as the "English Blacksmith's Clock." It has the very earliest application of the pendulum. The pendulum is less than 3 inches long and is hung on the verge, or pallet axle, and beats 222 per minute. This clock may be safely put at 250 years old, and contains nothing invented since that date. Wheels are cast brass and all teeth laboriously filed out by hand. Pinions are solid with the axles, or "staffs," and also filed out by hand. It is put together, generally by mortise, tenon and cotter, but it has four original screws all made by hand with the file. How did he thread the holes for these screws? Probably made a tap by hand as he made the screws. But the most remarkable feature is the fact that no lathe was used in forming any part--all staffs, pinions and pivots being filed by hand. This is simply extraordinary when it is pointed out that a little dead center lathe is the simplest machine in the world, and he could have made one in less than a day and saved himself weeks of hard labor. It is probable that he had great skill in hand work and that learning to use a lathe would have been a great and tedious effort for him. So we have a complete striking clock made by a man so poor that he had only his anvil, hammer and file. The weights are hung on cords as thick as an ordinary lead-pencil and pass over pulleys having spikes set around them to prevent the cords from slipping. The weights descend 7 feet in 12 hours, so they must be pulled up--not wound up--twice a day. The single hour hand is a work of art and is cut through like lace. Public clocks may still be seen in Europe with only one hand. Many have been puzzled by finding that old, rudely made clocks often have fine dials, but this is not remarkable when we state that art and engraving had reached a high level before the days of clocks.

[Illustration: THE LARGEST CLOCK IN THE WORLD

Courtesy of Colgate and Company.

THE HANDS OF THE LARGEST CLOCK IN THE WORLD--ON THE ROOF OF THE COLGATE FACTORY.

This big clock faces the giant office buildings of down-town New York. Its dial is 38 feet in diameter and can be read easily at a distance of three miles, so that passengers on the incoming liners pick out the clock as one of their first sights of New York.

The next largest clock (on the Metropolitan Tower) is 26½■ feet in diameter; the Westminster clock of London, 22½■ feet.

The great clock weighs approximately 6 tons. The minute hand, 20 feet long, travels at its point 23 inches every minute; more than one-half mile each day.

The bed of this clock is 4 feet in length, the wheels and gears being made of bronze and pinions of hardened steel. The time train occupies about one-third of the bedplate, and has a main time wheel measuring 18½■ inches in diameter. This train is equipped with Dennison's double three-legged gravity escapement, which was invented by Sir Edmund Becket, chiefly for use on the famous Westminster clock, installed in the Parliament Buildings, in London, England. The use of this escapement is most advantageous for a gigantic clock of this kind as it allows the impulse given the pendulum rod to be always constant, and therefore does not permit any change of power or driving force of the clock to affect its time-keeping qualities.

It requires about 600 pounds of cast-iron to propel this time train, and the clock is arranged to run eight days without winding. The gravity arms of the escapement are fastened at a point very near the suspension spring, and the arms are fitted with bronze roller beat pins.

The dial contains 1134 square feet, or about one thirty-fifth of an acre. The numerals consist of heavy black strokes, 5 feet 6 inches long and 30 inches wide at the outer end, tapering to a point at the inner end. The circumference of the dial is approximately 120 feet. The distance from center to center of numerals is 10 feet, and the minute spaces are 2 feet.

The background on dial is painted white, and in the daytime the black numerals show up distinctly. At night the numerals, or hour marks, are designated by a row of incandescent bulbs placed in a trough 5 inches wide and 5 inches deep. The hands at night are outlined with incandescent electric lights, there being 27 lamps on the hour hand and 42 lamps on the minute hand.]

[Illustration: THE MACHINERY WHICH RUNS A BIG CLOCK]

This picture shows the machinery necessary to operate a large modern tower clock.

The mechanism is held in place and confined entirely within a cast-iron structure which is firmly bolted to the floor. The wheels are composed of bronze, the pinions of steel (hardened) and the gears are machine cut. At the front of the clock is a small dial which enables one to tell exactly the position of the hands on the outside dials, and there is also a second hand to permit of very close regulation and adjustment.

Three ways are provided for the regulation. First by a knurled screw at the top of bed frame. Second by a revolving disc at the bottom of the pendulum ball. Very often by either of these two methods it is impossible to bring the clock to fractional seconds, and in order to permit of a nicety of adjustment there is a cup fitted at the top of the ball so that by inserting or taking out lead pellets, the rating can be brought to absolute time.

INDEPENDENCE HALL, PHILADELPHIA]

[Illustration: NEW YORK CITY HALL]

Where Does the Day Begin?

To understand this subject we must first appreciate that a day as we think of it is a division of time made by man for the purpose of his own reckoning. So far as the beginning of day is concerned, it begins at a different place in the world every hour; yes, every minute and every second in the day. As, however, the distance in feet where the day begins from one minute to another is so short that we can hardly notice it in such short measurements of time, we will look at the answer to the question from hour to hour. When you understand the subject from that point you can yourself see that the day actually begins at a different point of the earth every minute and every second of time.

How Much of the Earth Does the Sun Shine on at One Time?

The sun is shining on some part of the earth all the time and the shining of the sun makes the difference between day and night. Wherever the sun is shining it is day-time, and where the sun is not shining it is night-time.

To illustrate we will make use of an ordinary orange and a lighted gas jet. Let us take a long hat-pin and stick it through the orange from stem to stem. Now hold the orange by the ends of the hat-pin up before the lighted gas jet. You will notice that one-half of the orange is lighted, while the other half is dark. Of course, it is the half of the orange away from the light that is dark. Now, revolve the orange slowly on the hat-pin axis toward the light. When you have turned the orange half way round the part that was formerly dark is now lighted up and the other part is now dark.

Now examine closely and you will see that just one-half of the orange is lighted at one time and the other half is dark. You revolve the orange in front of the light slowly and a portion of the surface of the orange is always coming into the light, while a corresponding portion of it on the opposite side is constantly going into the dark. In other words, whatever the speed at which you revolve the orange toward the light, one-half of it is always light and the other half is always dark.

This is exactly what happens in the relation of the earth to the sun every day. One-half of the earth, which is continually revolving on its axis, is facing the sun, and is, therefore, in the daylight, while the other half of the earth’s surface is in darkness, because the light from the sun does not strike any portion of it. If the earth did not revolve one-half of it would always be in day-time, while the other half would be continually having night-time. As the earth is always moving or revolving the half where it is day-time is constantly changing, so that the day is beginning on one-half of the earth’s surface every second of the day. Actually, of course, then, if you live on the east side of town day begins with you a little sooner than with your chum who lives on the west side of town. We have come to measure the beginning of day as sunrise and the beginning of night as sunset, wherever we happen to be.

For convenience in setting clocks and in measuring time we do not take into consideration these very slight differences in the rising and setting of the sun, but set our clocks all alike in different parts of the same town or city to avoid confusion. In fact, in order to overcome the difficulties and confusions arising in reckoning the time of the clock in different localities, and still keep the beginning of what we call day-time constant with the hands of the clock, we have agreed upon what we call standard time. We agreed upon this system of fixing standard time because the actual sun time by which people set their clocks up to a few years ago led to so

many mistakes in catching trains, keeping engagements and other misunderstandings where the question of time was involved. Then when this system of standard time was adopted the confusion became even worse, and the mistakes and misses more numerous, because some people insisted on setting their clocks to standard time and others insisted on sticking to the old sun time schedule. So you could never tell by looking at the clock what time it really was unless they put a sign on the clock saying what kind of time they were going by. Finally, however, most of the people came to appreciate that it would be a good idea to use one uniform system of setting the clocks and of having them in harmony in a sense with the other clocks in the world, and the adoption of the standard time plan became universal. To make this system practical and effective, certain points about equally distant from each other were selected, at which point

Where Is the Hour Changed?

the hour would change for all points within that zone. Under this system all timepieces in any one zone point to the same hour. So the clock time changes only as you go east or west. All points on a north and south line have the same time as the zone in which it is located.

For convenience in adjusting the time in America the country was divided into four east and west zones. The first zone takes in everything on a straight north and south line east of Pittsburg, and is called Eastern time. The second zone extends from Pittsburg to Chicago, and is called Central time; the third zone extends from Chicago to Denver, and is called Mountain time; while the fourth zone extends from Denver to the Pacific Ocean. These selections were made because the sun actually rises about one hour later in Pittsburg than in New York; one hour later in Chicago than in Pittsburg; one hour later in Denver than in Chicago, and one hour later on the Pacific Coast than in Denver. Under this plan when it is nine o’clock in New York it is only eight o’clock at Pittsburg and all points in the Central zone; seven o’clock in all points in the Mountain zone; six o’clock in Denver and five o’clock in San Francisco. As you keep travelling westward you drop one hour of the clock time in every zone, and as under this system the earth’s east to west distance is divided into twenty-four such zones, if you went west entirely around the world you would lose a whole day of clock time.

If, however, you went around the world from west to east in the same manner you would gain a whole day.

Where Does the Day Change?

This system of agreeing on fixed places where the hour changes made it necessary to also fix a point where for the purposes of the calendar the day also changes. This imaginary north and south line is fixed upon at 180 degrees west longitude, which would cut the Pacific Ocean in two. This line makes it possible for a person to travel all day before approaching this line and then find himself after crossing it travelling all the next day with the same name for the day of the week. Thus he could spend all of Sunday travelling toward the International Day Line, as this is called, and after crossing it spend another Sunday, which would be the next day, going away from it. This would give him the novel experience of having two Sundays on successive days. The same thing would happen if he were travelling to the Day Line on Monday, Tuesday, Wednesday, Thursday, Friday or Saturday. He would live through two succeeding days of the same name in the same week, one right after the other. This would be in going westward.

If you were traveling eastward and crossed the International Day Line on Sunday at midnight you would lose a day completely out of the week, for when you woke up the next morning it would be Tuesday.

Why Do We Cook the Things We Eat?

We have several reasons for doing this. The first and most important reason to us is that the application of heat to food makes it more easy to digest. Other reasons are that when cooked our food is more palatable; the process of cooking kills all microbes, which, if taken into our bodies alive, would give us diseases, and also it is easier for us to chew food that has been cooked.

[Illustration: WONDERS PERFORMED BY ELECTRIC LIFT MAGNET

This picture shows the construction of a successful electric lift magnet. This device, by means of magnetic attraction, fastens itself to practically all kinds of iron and steel without the aid of slings, cables or chains.]

The Story in a Magnet

What Makes an Electro Magnet Lift Things?

The working parts of an electric lift magnet are as follows:

A Shell.--This is a steel casting heavily ribbed on the top for strength, and also to assist in radiating the heating effect from the coil.

It is usually made circular in shape, the outside rim forming one pole, while the lug in the center forms the other. The coil fits in between these poles, thus making a magnet similar to the ordinary horseshoe type.

A Bottom Plate.--The under side of the magnet is closed by a very tough and hard non-magnetic steel plate, in order to protect the coil.

As well as being non-magnetic, this plate also has sufficient strength to resist the severe wear to which a magnet is necessarily subjected.

A Terminal Box.--A one-piece heavily-constructed steel casting bolted to the top of the shell, containing and protecting the brass sockets into which the wires from the coil terminate, forms the Terminal Box.

The sockets are made to receive plugs placed on the end of the conductor wire, by which the magnet is connected with the generator.

A Coil.--This consists of a round insulated wire which is passed, while being wound, through a cement-like substance, heavily coating each individual strand.

A low voltage of current is then passed through the coil, a sufficient length of time, to thoroughly dry out and bake the coating. This renders the magnet absolutely fireproof, eliminating all danger of short circuiting of the coil.

When finished it is well taped to protect the outside wire from becoming chafed.

The coil is made slightly smaller than the inside dimensions of the shell and the remaining space is filled with an impregnating compound, which hardens to the consistency of pitch.

This renders the coil thoroughly waterproof; also forms a cushion to prevent injury from the severe jars and shocks, received when dropping a magnet on its load.

A Controller.--The rapidity with which it is necessary to turn current on and off while operating a magnet, creates what is called a “back kick.” Unless this is dissipated quickly it is very destructive to the coil.

A special controller dissipates this back kick through a set of resistance coils placed in the controller. By means of an automatic arrangement, connection with these coils is made instantly upon breaking the current between the magnet and generator.

A system of control used prevents undue heating of the coil. This enables the magnet to lift as large a load after a long steady run as at the start.

What Is a Lodestone?

A lodestone is a variety of the mineral named magnetite which is a natural magnet. The name magnet comes from the name of the mineral magnetite and this in turn derived its name from the fact that it was first discovered in Magnesia. The word magnet really means the “Stone of Magnesia.”

A lodestone is one of the mysteries of nature. Its properties can more nearly be understood if we examine an artificial magnet, which is generally made in the form of either a straight bar or a shoe. An artificial magnet is made of iron. If you drop a bar magnet into a box of iron filings, the filings attach themselves to the bar. If you examine it closely you observe that most of the filings attach themselves to the ends of the bar. Therefore we call the ends of the bar the poles of the magnet.

If you suspend a magnetic needle at its center of gravity so that it is absolutely free to turn, you will soon find one end of the needle pointing north and the other south of course. The end which is pointed toward the north is called the north pole and the other the south pole. If you have a horse-shoe magnet, you can demonstrate this for yourself. Rub the end of your magnet over a sewing

needle and oil the needle so that when you lay it on the surface of a glass of water it will float. Then look at it closely. You will see the needle slowly turn until finally it becomes quite still. If you have a compass at hand so that you know surely which is north and which is south, you will find one end of the needle pointing north and the other south. You can then place the end of your magnet against the outside of the glass and draw the needle toward your magnet. Your horse-shoe magnet has its north and south poles close together.

If you have a bar magnet and the end of the needle with the eye in it is pointing north, you can drive the needle on the surface of the water away from you by touching the outside of the glass opposite that end of the needle with the north pole of your magnet. On the other hand, if you reverse the experiment and place the south pole of your magnet to the side of the glass, the needle will come toward the magnet. In other words then the like poles of a magnet repel each other and the unlike poles attract each other.

Another interesting way to show this is to take two lodestones or two magnets and let a lot of iron filings attach themselves to the ends of them. Then when you have done this, point the two north poles of the magnets or lodestones at each other close together. You will be intensely interested in seeing how quickly the mysterious something that is in the magnets makes the filings on the two ends of the magnet try to get away from each other. On the other hand when you put a north and south pole together, they form a union of the iron filings.

Another strange thing about a magnet is that if you break it in two, each half will be a complete magnet in itself with a north and south pole also, and this is true no matter how many times you break it into pieces. From this we learn that each tiny particle or molecule throughout the bar is a magnet by itself.

[Illustration: WHAT A LODESTONE IS

This is a picture of a complete electro magnet. The magnet is attached to the arm of a crane by the loop in the center and when the magnet then comes in contact with any kind of iron or steel it lifts it as soon as the current is turned on. By making the electric current stronger, greater weight can be lifted. Many tons of material can be lifted at one time. An electro magnet will do the work of many men at much less cost.]

[Illustration: In this picture we see the magnet lifting a great weight of miscellaneous pieces of scrap iron. As many as twenty tons can be lifted and transferred from one place to another at one time.]

Some things can be magnetized while others cannot. Many substances have not the property of magnetizing other substances when they have once been attracted by a magnet. These are called magnetic substances. They remain magnetized only as long as they are in touch with the magnet; other substances when once magnetized become permanent magnets. Steel and lodestone have this faculty. A compass needle is an artificial magnet which becomes a permanent magnet when rubbed with a magnet.

What Is Electricity?

If you pass a hard rubber comb through your hair, in frosty weather, a crackling sound is produced, and the individual hairs show a tendency to stick to the comb. After being drawn through your hair a few times, you may notice that the comb has become charged with electricity. This electricity is produced by friction. Not only rubber but many other substances become electrified by friction, such as a bar of sealing wax rubbed with flannel, or a glass rod rubbed with silk, will show the same qualities, and these simple experiments teach us many of the fundamental facts about electricity.

Some simple experiments will be found instructive and interesting. Rub with flannel a stick of sealing wax until it is electrified and then bring it close to a pith ball which should be hung by a silk thread. The pith ball will at once be attracted to the sealing wax, and, if brought quite close, the ball will adhere to the wax for a few moments, and then fly away from it. The ball will now be repelled by the sealing wax instead of being drawn toward it. Now take a glass rod, rub it with a silk cloth after drying it thoroughly. When the pith ball is brought close to the glass rod it also will at first be attracted toward the glass and, if brought in contact with the glass, the pith ball will adhere as before. It will also then fly away in the same way it did from the sealing wax. Repeat these experiments with the sealing wax now and you will find the ball will be attached, as it was at first, but if it touches the wax it will again adhere for a moment and then fly away. By using the sealing wax and glass rod alternately and bringing them into contact with the pith ball, you discover that when it is attracted by one, it is repelled by the other, and that, after it has been in contact with either for a few moments it is no longer attracted by it.

We learn thus that the electricity in the glass and the sealing wax are not the same. To distinguish the two kinds of attraction, we say the glass is charged with positive, or vitreous electricity, while the charge on the sealing wax is called negative, or resinous electricity.

When the pith ball was touched with the sealing wax, it became filled with negative electricity, and was then no longer attracted by the wax, but was repelled by it and attracted by the glass rod; but when the ball had been filled with positive electricity, it was repelled by the glass and attracted by the wax. We conclude from these facts that bodies filled with the same kind of electricity repel each other, while bodies filled with opposite kinds of electricity attract each other.

When two substances are charged, as we say, with electricity of opposite kinds and are brought into contact, and left so for some time, the two charges disappear, one appearing to neutralize the other. From this, we conclude, and rightly, that any substance not electrified, contains equal amounts both positive and negative electricity. When, therefore, we rub a piece of glass with silk, we are not creating electricity, but only separating the different kinds. The positive electricity adheres to the glass, and the negative remains behind, on the silk. In the same manner, when we electrify sealing wax with flannel the negative kind remains in the sealing wax and the flannel becomes charged with the positive. Whenever a body is electrified by friction, both kinds of electricity are produced; it is impossible to produce one kind without the other.

[Illustration: WHAT ELECTRICITY IS

Magnets are particularly valuable in lifting raw material in a steel mill. The red-hot pig-iron, from which steel is made, can be handled easily in this way, whereas it would be impossible to handle same by hand. Sometimes great quantities of iron are broken up by the magnet. A weight of many tons is lifted by the magnet and allowed to fall on the material to be broken up. The weight falls as soon as the current is turned off.]

[Illustration:

Weight of wheel, 8160 lbs.

Pieces of machinery which cannot be lifted by men on account of their great weight and shape are handled easily.]

You must rub the entire glass rod or bar of sealing wax to electrify the whole of it. If only a part of the glass rod or sealing wax is rubbed, only that part becomes electrified, as may be shown by trying to attract a pith ball with the part that has not been rubbed.

~WHAT GOOD AND BAD CONDUCTORS OF ELECTRICITY ARE~

If, however, the charged part of the sealing wax is brought into contact with a metal rod resting on, say, a drinking glass, the rod becomes charged, not only where it is brought into contact, but all over its surface. Substances over which electricity flows readily are called conductors of electricity. All metals are of this kind. Things like glass and sealing wax over which electricity does not flow readily, are called non-conductors, or insulators. Water, the human body, and the earth are good conductors and rubber, porcelain, most resins, and dry air are non-conductors.

You have already learned that substances charged with opposite kinds of electricity attract each other, and substances charged with the same kind repel each other. We will try to discover why substances charged with either kind of electricity attract small light objects, such as pith balls, when these latter are not charged with electricity. As we have discovered, all substances which have remained undisturbed have both kinds of electricity present in them, in equal amounts. Now, when an uncharged body is brought near a charged body, the two kinds of electricity in the uncharged body have a tendency to separate. The kind opposite in character, to that on the charged body, is attracted toward the charged body, and the other kind is repelled. Thus, if our bar of sealing wax, charged with, let us say, negative electricity, is brought near a pith ball, the positive electricity in the ball is attracted to the side nearest the scaling wax, and the negative electricity is repelled to the farther side. As the positive electricity on the pith is nearer to the scaling wax than the negative, its attraction for the negative charge, on the sealing wax, is stronger than the repulsion between the negative electricities of the two objects, and consequently, the ball is attracted to the sealing wax. If the charged sealing wax i

To ANNIE FISCHER IN DEEPEST GRATITUDE

AUTHOR'S PREFACE

"The Decay and the Restoration of Civilization" is the first part of a complete philosophy of civilization with which I have been occupied since the year 1900.

The second part, entitled "Civilization and Ethics", will appear immediately. The third is called "The World-View_(_*_)_ of Reverence for Life". The fourth has to do with the civilized State.

That over which I have toiled since 1900 has been finally ripened in the stillness of the primeval forest of Equatorial Africa. There, during the years 1914-17, the clear and definite lines of this philosophy of civilization have been developed.

The first part, "The Decay and the Restoration of Civilization", is a kind of introduction to the philosophy of civilization. It states the problem of civilization.

Entering on the question as to what is the real essential nature of civilization, I come to the pronouncement that this is ultimately ethical. I know that in thus stating the problem as a moral one I [pg viii] shall surprise and even disgust the spirit of our times, which is accustomed to move amidst æsthetic, historical and material considerations. I imagine, however, that I am myself enough of an artist and also of an historian to be able to comprehend the æsthetic and historical elements in civilization, and that, as a modern physician and surgeon, I am sufficiently modern to appreciate the glamour of the technical and material attainments of our age.

Notwithstanding this, I have come to the conviction that the æsthetic and the historical elements, and the magnificent extension of our material knowledge and power, do not themselves form the essence of civilization, but that this depends on the mental disposition of the individuals and nations who exist in the world. All other things are merely accompanying circumstances of civilization, which have nothing to do with its real essence.

Creative, artistic, intellectual, and material attainments can only show their full and true effects when the continued existence and development of civilization have been secured by founding civilization itself on a mental disposition which is truly ethical. It is only in his struggle to become ethical that man comes to possess real value as a personality; it is only under the influence of ethical

convictions that the various relations of human society are formed in such a way that individuals and peoples can [pg ix] develop in an ideal manner. If the ethical foundation is lacking, then civilization collapses, even when in other directions creative and intellectual forces of the strongest nature are at work.

This moral conception of civilization, which makes me almost a stranger amidst the intellectual life of my time, I express clearly and unhesitatingly, in order to arouse amongst my contemporaries reflection as to what civilization really is. We shall not succeed in re-establishing our civilization on an enduring basis until we rid ourselves completely of the superficial concept of civilization which now holds us in thrall, and give ourselves up again to the ethical view which obtained in the eighteenth century.

The second point which I desire should obtain currency is that of the connection between civilization and our theory of the universe. At the present time no regard is paid to this connection. In fact, the period in which we are living altogether misses the significance of having a theory of the universe. It is the common conviction nowadays, of educated and uneducated alike, that humanity will progress quite satisfactorily without any theory of the universe at all.

The real fact is that all human progress depends on progress in its theory of the universe, whilst, conversely, decadence is conditioned by a similar [pg x] decadence in this theory. Our loss of real civilization is due to our lack of a theory of the universe.

Only as we again succeed in attaining a strong and worthy theory of the universe, and find in it strong and worthy convictions, shall we again become capable of producing a new civilization. It is this apparently abstract and paradoxical truth of which I proclaim myself the champion.

Civilization, put quite simply, consists in our giving ourselves, as human beings, to the effort to attain the perfecting of the human race and the actualization of progress of every sort in the circumstances of humanity and of the objective world. This mental attitude, however, involves a double predisposition: firstly, we must be prepared to act affirmatively toward the world and life; secondly, we must become ethical.

Only when we are able to attribute a real meaning to the world and to life shall we be able also to give ourselves to such action as will produce results of real value. As long as we look on our existence in the world as meaningless, there is no point whatever in desiring to effect anything in the world. We become workers for that universal spiritual and material progress which we call civilization only in so far as we affirm that the world and life possess some sort of meaning, or, which is the same thing, only in so far as we think optimistically.

[pg xi]

Civilization originates when men become inspired by a strong and clear determination to attain progress, and consecrate themselves, as a result of this determination, to the service of life and of the world. It is only in ethics that we can find the driving force for such action, transcending, as it does, the limits of our own existence.

Nothing of real value in the world is ever accomplished without enthusiasm and self-sacrifice.

But it is impossible to convince men of the truth of world- and life-affirmation and of the real value of ethics by mere declamation. The affirmative and ethical mentality which characterizes these beliefs must originate in man himself as the result of an inner spiritual relation to the world. Only then will they accompany him as strong, clear, and constant convictions, and condition his every thought and action.

To put it in another way: world- and life-affirmation must be the products of thought about the world and life. Only as the majority of individuals attain to this result of thought and continue under its influence will a true and enduring civilization make progress in the world. Should the mental disposition towards world- and life-affirmation and towards ethics begin to wane, or become dim and obscured, we shall be incapable of working for true civilization, nay, more, we shall be unable even to [pg xii] form a correct concept of what such civilization ought to be.

And this is the fate which has befallen us. We are bereft of any theory of the universe. Therefore, instead of being inspired by a profound and powerful spirit of affirmation of the world and of life, we allow ourselves, both as individuals and as nations, to be driven hither and thither by a type of such affirmation which is both confused and superficial. Instead of adopting a determined ethical attitude, we exist in an atmosphere of mere ethical phrases or declare ourselves ethical sceptics.

How is it that we have got into this state of lacking a theory of the universe? It is because hitherto the world- and life-affirming and ethical theory of the universe had no convincing and permanent foundation in thought. We thought again and again that we had found such a basis for it; but it lost power again and again without our being aware that it was doing so, until, finally, we have been obliged, for more than a generation past, to resign ourselves more and more to a complete lack of any world-theory at all.

Thus, in this introductory part of my work, I proclaim two truths and conclude with a great note of interrogation. The truths are the following: The basic ethical character of civilization, and the connection between civilization and our theories of [pg xiii] the universe. The question with which I conclude is this: Is it at all possible to find a real and permanent foundation in thought for a theory of the universe which shall be both ethical and affirmative of the world and of life?

The future of civilization depends on our overcoming the meaninglessness and hopelessness which characterize the thoughts and convictions of men to-day, and reaching a state of fresh hope and fresh determination. We shall be capable of this, however, only when the majority of individuals discover for themselves both an ethic and a profound and steadfast attitude of world- and life-affirmation, in a theory of the universe at once convincing and based on reflection.

Without such a general spiritual experience there is no possibility of holding our world back from the ruin and disintegration towards which it is being hastened. It is our duty then to rouse ourselves to fresh reflection about the world and life.

In “Civilization and Ethics”, the second part of this philosophy of civilization, I describe the road along which thought has led me to world- and life-affirmation and to ethics. The root-idea of my theory of the universe is that my relation to my own being and to the objective world is determined by reverence for life. This reverence for life is given as an element of my will-to-live, and becomes clearly [pg xiv] conscious of itself as I reflect about my life and about the world. In the mental attitude of reverence for life which should characterize my contact with all forms of life, both ethics and world- and life-affirmation are involved. It is not any kind of insight into the essential nature of the world which determines my relation to my own existence and to the existence which I encounter in the world, but rather only and solely my own will-to-live which has developed the power of reflection about itself and the world.

The theory of the universe characterized by reverence for life is a type of mysticism arrived at by self-consistent thought when persisted in to its ultimate conclusion. Surrendering himself to the guidance of this mysticism, man finds a meaning for his life in that he strives to accomplish his own spiritual and ethical self-fulfilment, and, simultaneously and in the same act, helps forward all the processes of spiritual and material progress which have to be actualized in the world.

I do not know how many, or how few, will allow themselves to be persuaded to travel with me on the road indicated above. What I desire above all things—and this is the crux of the whole affair—is that we should all recognize fully that our present entire lack of any theory of the universe is the ultimate source of all the catastrophes and misery of [pg xv] our times, and that we should toil in concert for a theory of the universe and of life, in order that thus we may arrive at a mental disposition which shall make us really and truly civilized men.

It was a great joy to me to be afforded the opportunity of putting forward, in the _Dale Lectures_, delivered in Oxford, the views on which this philosophy of civilization is based.

I would tender my deepest thanks to my friends, Mr. C. T. Campion, M.A., now of Grahamstown, South Africa, and Dr. J. P. Naish, of Oxford. Mr. Campion is the translator of this first part of the “Philosophy of Civilization”. Dr. Naish has seen the book through the press and translated this preface.

THE DECAY AND THE RESTORATION OF CIVILIZATION

CHAPTER I

HOW PHILOSOPHY IS RESPONSIBLE FOR THE COLLAPSE OF CIVILIZATION

Our self-deception as to the real conditions of our civilization. The collapse of the theory of the universe on which our ideals were based. The superficial character of modern philosophizing.

We are living to-day under the sign of the collapse of civilization. The situation has not been produced by the war; the latter is only a manifestation of it. The spiritual atmosphere has solidified into actual facts, which again react on it with disastrous results in every respect. This interaction of material and spiritual has assumed a most unhealthy character. Just below a mighty cataract we are driving along in a current full of formidable eddies, and it will need the most gigantic efforts to rescue the vessel of our fate from the dangerous side channel into which we have [pg 002] allowed it to drift, and bring it back into the main stream, if, indeed, we can hope to do so at all.

We have drifted out of the stream of civilization because there was amongst us no real reflection upon what civilization is. It is true that at the end of the last century and the beginning of this there appeared a number of works on civilization with the most varied titles; but, as though in obedience to some secret order, they made no attempt to settle and make clear the conditions of our intellectual life, but devoted themselves exclusively to its origin and history. They gave us a relief map of civilization marked with roads which men had observed or invented, and which led us over hill and dale through the fields of history from the Renaissance to the twentieth century. It was a triumph for the historical sense of the authors. The crowds whom these works instructed were filled with satisfied contentment when they understood that their civilization was the organic product of so many centuries of the working of spiritual and social forces, but no one worked out and described the content of our spiritual life. No one tested its value from the point of view of the nobility of its ideas, and its ability to produce real progress.

Thus we crossed the threshold of the twentieth century with an unshakable conceit of ourselves, [pg 003] and whatever was written at that time about our civilization only confirmed us in our ingenuous belief in its high value. Anyone who expressed doubt was regarded with astonishment. Many, indeed, who were on the road to error, stopped and returned to the main road again because they were afraid of the path which led off to the side. Others continued along the main road, but in silence; the understanding and insight which were at work in them only condemned them to isolation.

It is clear now to everyone that the suicide of civilization is in progress. What yet remains of it is no longer safe. It is still standing, indeed, because it was not exposed to the destructive pressure which overwhelmed the rest, but, like the rest, is built upon rubble, and the next landslide will very likely carry it away.

But what was it that preceded and led up to this loss of power in the innate forces of civilization?

The age of the Illuminati and of rationalism had put forward ethical ideals, based on reason, concerning the development of the individual to true manhood, his position in society, the material and spiritual problems which arose out of society, the relations of the different nations to each other, and their issue in a humanity which should be united in [pg 004] the pursuit of the highest moral and spiritual objects. These ideals had begun, both in philosophy and in general thought, to get into contact with reality and to alter the general environment. In the course of three or four generations there had been such progress made, both in the ideas underlying civilization and in their material embodiment, that the age of true civilization seemed to have dawned upon the world and to be assured of an uninterrupted development.

But about the middle of the nineteenth century this mutual understanding and co-operation between ethical ideals and reality began to break down, and in the course of the next few decades it disappeared more and more completely. Without resistance, without complaint, civilization abdicated. Its ideas lagged behind, as though they were too exhausted to keep pace with it. How did this come about?

* * * * *

The decisive element in the production of this result was philosophy's renunciation of her duty.

In the eighteenth century and the early part of the nineteenth it was philosophy which led and guided thought in general. She had busied herself with the questions which presented themselves to mankind at each successive period, and had kept the [pg 005] thought of civilized man actively reflecting upon them. Philosophy at that time included within herself an elementary philosophizing about man, society, race, humanity and civilization, which produced in a perfectly natural way a living popular philosophy that controlled the general thought, and maintained the enthusiasm for civilization.

But that ethical, and at the same time optimistic, view of things in which the Illuminati and rationalism had laid the foundations of this healthy popular philosophy, was unable in the long run to meet the criticism levelled at it by pure thought. Its naïve dogmatism raised more and more prejudice against it. Kant tried to provide the tottering building with new foundations, undertaking to alter the rationalistic view of things in accordance with the demands of a deeper theory of knowledge, without, however, making any change in its essential spiritual elements. Goethe, Schiller and other intellectual giants of the age, showed, by means of criticism both kindly and malicious, that rationalism was rather popular philosophy than real philosophy, but they were not in a position to put into the place of what they destroyed anything new which could give the same effective support to the ideas about civilization which were current in the general thought of the time.

[pg 006]

Fichte, Hegel, and other philosophers, who, for all their criticism of rationalism, paid homage to its ethical ideals, attempted to establish a similar ethical and optimistic view of things by speculative methods, that is by logical and metaphysical discussion of pure being and its development into a universe. For three or four decades they succeeded in deceiving themselves and others with this supposedly creative and inspiring illusion, and in doing violence to reality in the interests of their theory of the universe. But at last the natural sciences, which all this time had been growing stronger and stronger, rose up against them, and, with a plebeian enthusiasm for the truth of reality, reduced to ruins the magnificent creations of their imagination.

Since that time the ethical ideas on which civilization rests have been wandering about the world, poverty-stricken and homeless. No theory of the universe has been advanced which can give them a solid foundation; in fact, not one has made its appearance which can claim for itself solidity and inner consistency. The age of philosophic dogmatism had come definitely to an end, and after that nothing was recognized as truth except the science which described reality. General theories of the universe no longer appeared as fixed stars; they [pg 007] were regarded as resting on hypothesis, and ranked no higher than comets.

The same weapon which struck down the dogmatism of knowledge about the universe struck down also the dogmatic enunciation of spiritual ideas. The early simple rationalism, the critical rationalism of Kant, and the speculative rationalism of the great philosophers of the nineteenth century had all alike done violence to reality in two ways. They had given a position above that of the facts of science to the views which they had arrived at by pure thought, and they had also preached a series of ethical ideals which were meant to replace by new ones the various existing relations in the ideas and the material environment of mankind. When the first of these two forms of violence was proved to be a mistaken one, it became questionable whether the second could still be allowed the justification which it had hitherto enjoyed. The doctrinaire methods of thought which made the existing world nothing but material for the production of a purely theoretical sketch of a better future were replaced by sympathetic attempts to understand the historical origin of existing things for which Hegel's philosophy had prepared the way.

With a general mentality of this description, a real combination of ethical ideals with reality was no [pg 008] longer possible; there was not the freedom from prejudice which that required, and so there came a weakening of the convictions which were the driving power of civilization. So, too, an end was put to that justifiable violence to human convictions and circumstances without which the reforming work of civilization can make no advance, because it was bound up with that other unjustifiable violence to reality. That is the tragic element in the psychological development of our spiritual life during the latter half of the nineteenth century.

Rationalism, then, had been dismissed; but with it went also the optimistic convictions as to the moral meaning of the universe and of humanity, of society and of man, to which it had given birth, though the conviction still exerted so much influence that no attention was paid to the catastrophe which had really begun.

* * * * *

Philosophy did not realize that the power of the ideas about civilization which had been entrusted to it was becoming a doubtful quantity. At the end of one of the most brilliant works on the history of philosophy which appeared at the close of the nineteenth century philosophy is defined as the process "by which there comes to completion, step by step, [pg 009] and with ever clearer and surer consciousness, that conviction about the value of civilization the universal validity of which it is the object of philosophy itself to affirm." But the author has forgotten the essential point, viz., that there was a time when philosophy did not merely convince itself of the value of civilization, but also let its convictions go forth as fruitful ideas destined to influence the general thought, while from the middle of the nineteenth century onwards these convictions had become more and more of the nature of hoarded and unproductive capital.

Once philosophy had been an active worker producing universal convictions about civilization. Now, after the collapse in the middle of the nineteenth century, this same philosophy had become a mere drawer of dividends, concentrating her activities far from the world on what she had managed to save. She had become a mere science, which sifted the results of the historical and natural sciences, and collected from them material for a future theory of the universe, carrying on with this object in view a learned activity in all branches of knowledge. At the same time she became more and more absorbed in the study of her own past. Philosophy came to mean practically the history of philosophy, but the creative spirit had left her. She became more and [pg 010] more a philosophy which contained no real thought. She reflected, indeed, on the results achieved by the individual sciences, but she lost the power of thought about fundamental problems.

She looked back with condescending pity on the rationalism which she had outstripped. She prided herself on being able to trace her descent through Kant, on having been shown by Hegel the inner meaning of history, and on being at work to-day in close sympathy with the natural sciences. But for all that she was poorer than the poorest rationalism, because she now carried on in imagination only, and not in reality, the recognized work of philosophy, which the latter had practised so zealously. Rationalism, for all its simplicity, had been a working philosophy, but philosophy herself had now become, for all her insight, merely a pedantic philosophy of degenerates. She still played, indeed, some sort of _rôle_ in schools and universities, but she had no longer any message for the great world.

In spite of all her learning, she had become a stranger to the world, and the problems of life which occupied men and the whole thought of the age had no part in her activities. Her way lay apart from the general spiritual life, and just as she derived no stimulus from the latter, so she gave none back. Refusing to concern herself with fundamental [pg 011] problems, she contained no fundamental philosophy which could become a philosophy of the people.

From this impotence came the aversion to all generally intelligible philosophizing which is so characteristic of her. Popular philosophy was for her merely a review, prepared for the use of the crowd, simplified, and therefore rendered inferior, of the results given by the individual sciences which she had herself sifted and put together in view of a future theory of the universe. She was wholly unconscious of several things, viz., that there is a popular philosophy which arises out of such a review; that it is just the province of philosophy to deal with the primary, deeper questions about which individuals and the crowd are thinking, or ought to be thinking, to apply to them more comprehensive and more thorough methods of thought, and then restore them to general currency; and, finally, that the value of any philosophy is in the last resort to be measured by its capacity, or incapacity, to transform itself into a living philosophy of the people.

Whatever is deep is also simple, and can be reproduced as such, if only its relation to the whole of reality is preserved. It is then something abstract, which secures for itself a many-sided life as soon as it comes into contact with facts.

[pg 012]

Whatever of inquiring thought there was among the general public was therefore compelled to languish, because our philosophy refused either to acknowledge or to help it. It found in front of it a deep chasm which it could not cross.

Of gold coinage, minted in the past, philosophy had abundance; hypotheses about a soon to be developed theological theory of the universe filled her vaults like unminted bullion; but food with which to appease the spiritual hunger of the present she did not

possess. Deceived by her own riches, she had neglected to plant any ground with nourishing crops, and therefore, ignoring the hunger of the age, she left the latter to its fate.

That pure thought never managed to construct a theory of the universe of an optimistic, ethical character, and to build up on that for a foundation the ideals which go to produce civilization, was not the fault of philosophy; it was a fact which became evident as thought developed. But philosophy was guilty of a wrong to our age in that it did not admit the fact, but remained wrapped up in its illusion, as though this were really a help to the progress of civilization.

The ultimate vocation of philosophy is to be the guide and guardian of the general reason, and it was her duty, in the circumstances of the time, to confess [pg 013] to our world that ethical ideals were no longer supported by any general theory of the universe, but were, till further notice, left to themselves, and must make their way in the world by their own innate power. She ought to have shown us that we have to fight on behalf of the ideals on which our civilization rests. She ought to have tried to give these ideals an independent existence by virtue of their own inner value and inner truth, and so to keep them alive and active without any extraneous help from a corresponding theory of the universe. No effort should have been spared to direct the attention of the cultured and the uncultured alike to the problem of the ideals of civilization.

But philosophy philosophized about everything except civilization. She went on working undeviatingly at the establishment of a theoretical view of the universe, as though by means of it everything could be restored, and did not reflect that this theory, even if it were completed, would be constructed only out of history and science, and would accordingly be unoptimistic and unethical, and would remain for ever an “impotent theory of the universe,” which could never call forth the energies needed for the establishment and maintenance of the ideals of civilization.

So little did philosophy philosophize about [pg 014] civilization that she did not even notice that she herself and the age along with her were losing more and more of it. In the hour of peril the watchman who ought to have kept us awake was himself asleep, and the result was that we put up no fight at all on behalf of our civilization.

[pg 015]

CHAPTER II

HINDRANCES TO CIVILIZATION IN OUR ECONOMIC AND SPIRITUAL LIFE

The unfree economic position of the modern man. The undeveloped condition of the modern man. The modern man’s want of humanity. The lack of spiritual independence in the man of to-day.

Even if the abdication of thought has been, as we have seen, the decisive factor in the collapse of our civilization, there are yet a number of other causes which combine with it to hinder our progress in this regard. They are to be found in the field of spiritual as well as in that of economic activity, and depend, above all, on the interaction between the two, an interaction which is unsatisfactory and continually becoming more so.

The capacity of the modern man for progress in civilization is diminished because the circumstances in which he finds himself placed injure him psychically and stunt his personality.

The development of civilization comes about—to put it quite generally—by individual men thinking out ideals which aim at the progress of the whole, and then so fitting them to the realities of life that [pg 016] they assume the shape in which they can influence most effectively the circumstances of the time. A man’s ability to be a pioneer of progress, that is, to understand what civilization is and to work for it, depends, therefore, on his being a thinker and on his being free. He must be the former if he is to be capable of comprehending his ideals and putting them into shape. He must be free in order to be in a position to launch his ideals out into the general life. The more completely his activities are taken up in any way by the struggle for existence, the more strongly will the impulse to improve his own condition find expression in the ideals of his thought. Ideals of self-interest then get mixed up with and spoil his ideals of civilization.

Material and spiritual freedom are closely bound up with one another. Civilization presupposes free men, for only by free men can it be thought out and brought to realization.

But among mankind to-day both freedom and the capacity for thought have been sadly diminished.

If society had so developed that a continually widening circle of the population could enjoy a modest, but well-assured, condition of comfort, civilization would have been much more helped than it has been by all the material conquests which are lauded in its name. These do, indeed, make [pg 017] mankind as a whole less dependent upon nature, but at the same time they diminish the number of free and independent lives. The artisan who was his own master becomes the factory hand through the compulsion of machinery. Because in the complicated business world of to-day only undertakings with abundant capital behind them can maintain their existence, the place of the small, independent dealer is being taken more and more completely by the employee. Even the classes which still possess a larger or smaller amount of property or maintain a more or less independent activity get drawn more and more completely into the struggle for existence because of the insecurity of present conditions under the economic system of to-day.

The lack of freedom which results is made worse still because the factory system creates continually growing agglomerations of people who are thereby compulsorily separated from the soil which feeds them, from their own homes and from nature. Hence comes serious psychical injury. There is only too much truth in the paradoxical saying that abnormal life begins with the loss of one's own field and dwelling-place.

Civilization is, it is true, furthered to a certain extent by the self-regarding ideals produced by the [pg 018] groups of people who unite and co-operate in defence of their similarly threatened interests in so far as they seek to obtain an improvement in their material, and thereby also in their spiritual, environment. But these ideals are a danger to the idea of civilization as such, because the form which they assume is either not at all, or very imperfectly, determined by the really universal interests of the community. The consideration of civilization as such is held back by the competition between the various self-regarding ideals which go under its name.

To the want of freedom we have to add the evil of overwork. For two or three generations numbers of individuals have been living as workers merely, not as human beings. Whatever can be said in a general way about the moral and spiritual significance of labour has no bearing on what they have to do. An excessive amount of labour is the rule to-day in every department of industry, with the result that the labourer's spiritual element cannot possibly thrive. This overwork hits him indirectly even in his childhood, for his parents, caught in the inexorable toils of work, cannot devote themselves to his up-bringing as they should. Thus his development is robbed of something which can never be made good, and later in life, when he himself is the slave of over-long hours, he feels more and [pg 019] more the need of external distractions. To spend the time left to him for leisure in self-cultivation, or in serious intercourse with his fellows or with books, requires a mental collectedness and a self-control which he finds very difficult. Complete idleness, forgetfulness, and diversion from his usual activities are a physical necessity. He does not want to think, and seeks not self-improvement, but entertainment, that kind of entertainment, moreover, which makes least demand upon his spiritual faculties.

The mentality of this mass of individuals, spiritually relaxed and incapable of self-collectedness, reacts upon all those institutions which ought to serve the cause of culture, and therewith of civilization. The theatre takes a second place behind the pleasure resort or the picture show, and the instructive book behind the diverting one. An ever increasing proportion of periodicals and newspapers have to accommodate themselves to the necessity of putting their matter before their readers in the shape which lets it be assimilated most easily. A comparison of the average newspapers of to-day with those of fifty or sixty years ago shows how thoroughly such publications have had to change their methods in this respect.

When once the spirit of superficiality has penetrated [pg 020] into the institutions which ought to sustain the spiritual life, these exercise on their part a reflex influence on the society which they have brought to this condition, and force on all alike this state of mental vacuity.

How completely this want of thinking power has become a second nature in men to-day is shown by the kind of sociability which it produces. When two of them meet for a conversation each is careful to see that their talk does not go beyond generalities or develop into a real exchange of ideas. No one has anything of his own to give out, and everyone is haunted by a sort of terror lest anything original should be demanded from him.

The spirit produced in such a society of never-concentrated minds is rising among us as an ever growing force, and it results in a lowered conception of what man should be. In ourselves, as in others we look for nothing but vigour in productive work and resign ourselves to the abandonment of any higher ideal.

When we consider this want of freedom and of mental concentration, we see that the conditions of life for the inhabitants of our big cities are as unfavourable as they could be. Naturally, then, those inhabitants are in most danger on their spiritual side. It is doubtful whether big cities [pg 021] have ever been foci of civilization in the sense that in them there has arisen the ideal of a man well and truly developed as a spiritual personality; to-day, at any rate, the condition of things is such that true civilization needs to be rescued from the spirit that issues from them and their inhabitants.

* * * * *

But, besides the hindrance caused to civilization by the modern man's lack of freedom and of the power of mental concentration, there is a further hindrance caused by his imperfect development. The enormous increase of human knowledge and power, in specialized thoroughness as well as in extent, necessarily leads to individual activities being limited more and more to well-defined departments. Human labour is organized and co-ordinated so that specialization may enable individuals to make the highest and most effective possible contribution. The results obtained are amazing, but the spiritual significance of the work for the worker suffers. There is no call upon the whole man, only upon some of his faculties, and this has a reflex effect upon his nature as a whole. The faculties which build up personality and are called out by comprehensive and varied tasks are ousted by the less comprehensive ones, which from this point of view are, in the [pg 022] general sense of the word, less spiritual. The artisan of to-day does not understand his trade as a whole in the way in which his predecessor did. He no longer learns, like the latter, to work the wood or the metal through all the stages of manufacture; many of these stages have already been carried out by men and machines before the material comes into his hands. Consequently his reflectiveness, his imagination, and his skill are no longer called out by ever varying difficulties in the work, and his creative and artistic powers are atrophied. In place of the normal self-consciousness which is promoted by work into the doing of which he must put his whole power of thought and his whole personality, there comes a self-satisfaction which is content with a fragmentary ability which, it may be admitted, is perfect, and this self-satisfaction is persuaded by its perfection in mastering details to overlook its imperfection in dealing with the whole.

In all professions, most clearly perhaps in the pursuit of science, we can recognize the spiritual danger with which specialization threatens not only individuals, but the spiritual life of the community. It is already noticeable, too, that education is carried on now by teachers who have not a wide enough outlook to make their scholars understand the interconnection of the individual sciences, and [pg 023] to be able to give them a mental horizon as wide as it should be.

Then, as if specialization and the organization of work, where it is unavoidable, were not already injurious enough to the soul of the modern man, it is pursued and built up where it could be dispensed with. In administration, in education, and in every kind of calling the natural sphere of activity is narrowed as far as possible by rules and superintendence. How much less free in many countries is the elementary school teacher of to-day compared with what he was once! How lifeless and impersonal has his teaching become as a result of all these limitations!

Thus through our methods of work we have suffered loss spiritually and as individuals just in proportion as the material output of our collective activity has increased. Here, too, is an illustration of that tragic law which says that every gain brings with it, somehow or other, a corresponding loss.

* * * * *

But man to-day is in danger not only through his lack of freedom, of the power of mental concentration, and of the opportunity for all-round development: he is in danger of losing his humanity.

The normal attitude of man to man is made very [pg 024] difficult for us. Owing to the hurry in which we live, to the increased facilities for intercourse, and to the necessity for living and working with many others in an overcrowded locality, we meet each other continually, and in the most varied relations, as strangers. Our circumstances do not allow us to deal with each other as man to man, for the limitations placed upon the activities of the natural man are so general and so unbroken that we get accustomed to them, and no longer feel our mechanical, impersonal intercourse to be something that is unnatural. We no longer feel uncomfortable that in such a number of situations we can no longer be men among men, and at last we give up trying to be so, even when it would be possible and proper.

In this respect, too, the soul of the townsman is influenced most unfavourably by his circumstances, and that influence, in its turn, works most unfavourably on the mentality of society.

Thus we tend to forget our relationship with our fellows, and are on the path towards inhumanity. Wherever there is lost the consciousness that every man is an object of concern for us just because he is man, civilization and morals are shaken, and the advance to fully developed inhumanity is only a question of time.

As a matter of fact, the most utterly inhuman [pg 025] thoughts have been current among us for two generations past in all the ugly clearness of language and with the authority of logical principles. There has been created a social mentality which discourages humanity in individuals. The courtesy produced by natural feeling disappears, and in its place comes a behaviour which shows entire indifference, even though it is decked out more or less thoroughly in a code of manners. The standoffishness and want of sympathy which are shown so clearly in every way to strangers are no longer felt as being really rudeness, but pass for the behaviour of the man of the world. Our society has also ceased to allow to all men, as such, a human value and a human dignity; many sections of the human race have become merely raw material and property in human form. We have talked for decades with ever increasing light-mindedness about war and conquest, as if these were merely operations on a chess-board; how was this possible save as the result of a tone of mind which no longer pictured to itself the fate of individuals, but thought of them only as figures or objects belonging to the material world? When the war broke out the inhumanity within us had a free course. And what an amount of insulting stuff, some decently veiled, some openly coarse, about the coloured races, has made its appearance during the last decades, and passed for truth and [pg 026] reason, in our colonial literature and our parliaments, and so become an element in general public opinion! Twenty years ago there was a discussion in one of our Continental parliaments about some deported negroes who had been allowed to die of hunger and thirst; and there was no protest or comment when, in a statement from the tribune, it was said that they “had been lost” (“_eingegangen_” or “_crêvé_”), as though it were a question of cattle!

In the education and the school books of to-day the duty of humanity is relegated to an obscure corner, as though it were no longer true that it is the first thing necessary in the training of personality, and as if it were not a matter of great importance to maintain it as a strong influence in our human race against the influence of outer circumstances. It has not been so always. There was a time when it was a ruling influence not only in schools, but in literature, even down to the book of adventures. Defoe’s hero, Robinson Crusoe, is continually reflecting on the subject of humane conduct, and he feels himself so responsible for loyalty to this duty that when defending himself he is continually thinking how he can sacrifice the smallest number of human lives; he is so faithful, indeed, to this duty of humanity, that the story of his adventures acquires thereby quite a peculiar character. Is [pg 027] there among works of this kind to-day a single one in which we shall find anything like it?

* * * * *

Another hindrance to civilization to-day is the over-organization of our public life.

While it is certain that a properly ordered environment is the condition and, at the same time, the result of civilization, it is also undeniable that, after a certain point has been reached, external organization is developed at the expense of spiritual life. Personality and ideas are then subordinated to institutions, when it is really these which ought to influence the latter and keep them inwardly alive.

If a comprehensive organization is established in any department of social life, the results are at first magnificent, but after a time they fall off. It is the already existing resources which are realized at the start, but later on the destructive influence of such organization on what is living and original is clearly seen in its natural results, and the more consistently the organization is enlarged, the more strongly its effect is felt in the repression of creative and spiritual activity. There are modern States which cannot recover either economically or spiritually from the paralysing effects of a concentration which dates from a very early period of their history.

[pg 028]

The conversion of a wood into a park and its maintenance as such may be a step towards carrying out several different objects, but it is all over then with the rich vegetation which would assure its future condition in nature’s own way.

Political, religious and economic associations aim to-day at forming themselves in such a way as will combine the greatest possible inner cohesion with the highest possible degree of external activity. Constitution, discipline, and everything that belongs to administration are brought to a perfection hitherto unknown. They attain their object, but just in proportion as they do so these centres of activity cease to work as living organizations, and come more and more to resemble perfected machines. Their inner life loses in richness and variety because the personalities of which they are composed must needs decay in character.

Our whole spiritual life nowadays has its course within organizations. From childhood up the man of to-day has his mind so full of the thought of discipline that he loses the sense of his own individuality and can only see himself as thinking in the spirit of some group or other of his fellows. A thorough discussion between one idea and another or between one man and another, such as constituted the greatness of the eighteenth century, is never met [pg 029] with now. But at that time fear of public opinion was a thing unknown. All ideas had then to justify themselves to the individual reason. To-day it is the rule—and no one questions it—always to take into account the views which prevail in organized society. The individual starts by taking it for granted that both for himself and his neighbours there are certain views already established which they cannot hope to alter, views which are determined by nationality, creed, political party, social position, and other elements in one's surroundings. These views are protected by a kind of taboo, and are not only kept sacred from criticism, but are not a legitimate subject of conversation. This kind of intercourse, in which we mutually abjure our natural quality as thinking beings, is euphemistically described as respect for other people's convictions, as if there could be any convictions at all where there is no thought.

The modern man is lost in the mass in a way which is without precedent in history, and this is perhaps the most characteristic trait in him. His diminished concern about his own nature makes him as it is susceptible, to an extent that is almost pathological, to the views which society and its organs of expression have put, ready made, into circulation. Since, over and above this, society, [pg 030] with its well-constructed organization, has become a power of as yet unknown strength in the spiritual life, man's want of independence in the face of it has become so serious that he is almost ceasing to claim a spiritual existence of his own. He is like a rubber ball which has lost its elasticity, and preserves indefinitely every impression that is made upon it. He is under the thumb of the mass, and he draws from it the opinions on which he lives, whether the question at issue is national or political or one of his own belief or unbelief.

Yet this abnormal subjection to external influences does not strike him as being a weakness. He looks upon it as an achievement, and in his unlimited spiritual devotion to the interests of the community he thinks he is preserving the greatness of the modern man. He intentionally exaggerates our natural social instincts into something fantastically great.

It is just because we thus renounce the indefeasible rights of the individual that our race can neither produce new ideas nor make current ones serviceable for new objects; its only experience is that prevailing ideas obtain more and more authority, take on a more and more one-sided development, and live on till they have produced their last and most dangerous consequences.

Thus we have entered on a new mediæval period. [pg 031] The general determination of society has put freedom of thought out of fashion, because the majority renounce the privilege of thinking as free personalities, and let themselves be guided in everything by those who belong to the various groups and cliques.

Spiritual freedom, then, we shall recover only when the majority of individuals become once more spiritually independent and self-reliant, and discover their natural and proper relation to those organizations in which their souls have been entangled. But liberation from the Middle Ages of to-day will be a much more difficult process than that which freed the peoples of Europe from the first Middle Ages. The struggle then was against external authority established in the course of history. To-day the task is to get the mass of individuals to work themselves out of the condition of spiritual weakness and dependence to which they have brought themselves. Could there be a harder task?

Moreover, no one as yet clearly perceives what a condition of spiritual poverty is ours to-day. Every year the spread of opinions which have no thought behind them is carried further by the masses, and the methods of this process have been so perfected, and have met with such a ready welcome, that our [pg 032] confidence in being able to raise to the dignity of public opinion the silliest of statements, wherever it seems necessary to get them currently accepted, has no need to justify itself before acting.

During the war the control of thought was made complete. Propaganda definitely took the place of truth.

With independence of thought thrown overboard, we have, as was inevitable, lost our faith in truth. Our spiritual life is disorganized, for the over-organization of our external environment leads to the organization of our absence of thought.

Not only in the intellectual sphere, but in the moral also, the relation between the individual and the community has been upset. With the surrender of his own personal opinion the modern man surrenders also his personal moral judgment.

In order that he may find good what the mass declares to be such, whether in word or deed, and may condemn what it declares to be bad, he suppresses the scruples which stir in him. He does not allow them to find utterance either with others or with himself. There are no stumbling-blocks which his feeling of unity with the herd does not enable him to surmount, and thus he loses his

judgment in that of the mass, and his own morality in theirs.

Above all, he is thus made capable of excusing [pg 033] everything that is meaningless, cruel, unjust, or bad in the behaviour of his nation. Unconsciously to themselves, the majority of the members of our barbarian civilised States give less and less time to reflection as moral personalities, so that they may not be continually coming into inner conflict with their fellows as a body, and continually having to get over things which they feel to be wrong.

Public opinion helps them by popularizing the idea that the actions of the community are not to be judged so much by the standards of morality as by those of expediency, but they suffer injury to their souls. If we find among men of to-day only too few whose human and moral sensibility is still undamaged, the chief reason is that the majority have offered up their personal morality on the altar of their country, instead of remaining at variance with the mass and acting as a force which impels the latter along the road to perfection.

Not only between the economic and the spiritual, then, but also between the mass of men and individuals, there has developed a condition of unfavourable action and reaction. In the days of rationalism and serious philosophy the individual got help and support from society through the general confidence in the victory of the rational and moral, which society never failed to acknowledge [pg 034] as something which explained and justified itself. Individuals were then carried along by the mass; we are stifled by it. The bankruptcy of the civilized State, which becomes more manifest every decade, is ruining the man of to-day. The demoralization of the individual by the mass is in full swing.

The man of to-day pursues his dark journey in a time of darkness, as one who has no freedom, no mental collectedness, no all-round development, as one who loses himself in an atmosphere of inhumanity, who surrenders his spiritual independence and his moral judgment to the organized society in which he lives, and who finds himself in every direction up against hindrances to the temper of true civilization. Of the dangerous position in which he is placed philosophy has no understanding, and therefore makes no attempt to help him. She does not even urge him to reflection on what is happening to himself.

The terrible truth that with the progress of history and the economic development of the world it is becoming not easier, but harder, to develop true civilization, has never found utterance.

[pg 035]

CHAPTER III

CIVILIZATION ESSENTIALLY ETHICAL IN CHARACTER

What is civilization? Origin of the unethical conception of civilization. Our sense of reality. Our historical sense. Nationalism. National civilization. Our misleading trust in facts and organization. The true sense for reality.

This question ought to have been pressing itself on the attention of all men who consider themselves civilized, but it is remarkable that in the world's literature generally one hardly finds that it has been put at all until to-day, and still more rarely is any answer given. It was supposed that there was no need for a definition of civilization, since we already possessed the thing itself. If the question was ever touched upon, it was considered to be sufficiently settled with references to history and the present day. But now, when events are bringing us inexorably to the consciousness that we live in a dangerous medley of civilization and barbarism, we must, whether we wish to or not, try to determine the nature of true civilization.

For a quite general definition we may say that civilization is progress, material and spiritual progress, on the part of individuals as of the mass.

[pg 036]

In what does it consist? First of all in a lessening of the strain imposed on individuals and on the mass by the struggle for existence. The establishment of as favourable conditions of living as possible for all is a demand which must be made partly for its own sake, partly with a view to the spiritual and moral perfecting of individuals, which is the ultimate object of civilization.

The struggle for existence is a double one: man has to assert himself in nature and against nature, and similarly also among his fellow-men and against them.

A diminution of the struggle is secured by strengthening the supremacy of reason over both external nature and human nature, and making it subserve as accurately as possible the ends proposed.

Civilization is then twofold in its nature: it realizes itself in the supremacy of reason, first, over the forces of nature, and, secondly, over the dispositions of men.

Which of these kinds of progress is most truly progress in civilization? The latter, though it is the least open to observation. Why? For two reasons. First, the supremacy which we secure by reason over external nature represents not unqualified progress, but a progress which brings with its advantages also disadvantages which may work in the direction of barbarism. The reason why the economic circumstances of our time endanger our civilization is to be sought for partly in the fact that we have pressed [pg 037] into our service natural forces which can be embodied in machines. But with that there must be such a supremacy of reason over the dispositions of men that they, and the nations which they form, will not use against one another the power which the control of these forces gives them, and thus plunge one another into a struggle for existence which is far more terrible than that between men in a state of nature.

A normal claim to be civilized can, then, only be reckoned as valid when it recognizes this distinction between what is essential in civilization and what is not.

Both kinds of progress can, indeed, be called spiritual in the sense that they both rest upon a spiritual activity in man, yet we may call the supremacy over natural forces material progress because in it material objects are mastered and turned to man's use. The supremacy of reason over human dispositions, on the other hand, is a spiritual achievement in another sense, in that it means the working of spirit upon spirit, _i.e._, of one section of the power of reflexion upon another section of it.

And what is meant by the supremacy of the reason over human dispositions? It means that both individuals and the mass let their willing be determined by the material and spiritual good of the whole and the individuals that compose it; that [pg 038] is to say, their actions are ethical. Ethical progress is, then, that which is truly of the essence of civilization, and has only one significance; material progress is that which is not of the essential at all, and may have a twofold effect on the development of civilization. This moral conception of civilization will strike some people as rationalistic and old-fashioned. It accords better with the spirit of our times to conceive of civilization as a natural manifestation of life in the course of human evolution, but one with most interesting complications. We are concerned, however, not with what is ingenious, but with what is true. In this case the simple is the true—the inconvenient truth with which it is our laborious task to deal.

* * * * *

The attempts to distinguish between civilization as what the Germans call "Kultur" and civilization as mere material progress aim at making the world familiar with the idea of an unethical form of civilization side by side with the ethical, and at clothing the former with a word of historical meaning. But nothing in the history of the word "civilization" justifies such attempts. The word, as commonly used hitherto, means the same as the German "Kultur", viz., the development of man to a state of higher organization and a higher [pg 039] moral standard. Some languages prefer one word; others prefer the other. The German usually speaks of "Kultur", the Frenchman usually of "civilisation", but the establishment of a difference between them is justified neither philologically nor historically. We can speak of ethical and unethical "Kultur" or of ethical and unethical "civilisation", but not of "Kultur" and "civilisation".

But how did it come about that we lost the idea that the ethical has a decisive meaning and value as part of civilization?

All attempts at civilization hitherto have been a matter of processes in which the forces of progress were at work in almost every department of life. Great achievements in art, architecture, administration, economics, industry, commerce, and colonization succeeded each other with a spiritual impetus which produced a higher conception of the universe. Any ebb of the tide of civilization made itself felt in the material sphere as well as in the ethical and spiritual, earlier, as a rule, in the former than in the latter. Thus in Greek civilization there set in as early as the time of Aristotle an incomprehensible arrest of science and political achievement, whereas the ethical movement only reached its completion in the following centuries in that great work of education which was undertaken in the ancient [pg 040] world by the Stoic philosophy. In the Chinese, Indian and Jewish civilizations ability in dealing with material things was from the start, and always remained, at a lower level than the spiritual and ethical efforts of these races.

In the movement of civilization which began with the Renaissance, there were both material and spiritual-ethical forces of progress at work side by side, as though in rivalry with each other, and this continued down to the beginning of the nineteenth century. Then, however, something unprecedented happened: man's ethical energy died away, while the conquests achieved by his spirit in the material sphere increased by leaps and bounds. Thus for several decades our civilization enjoyed the great advantages of its material progress while as yet it hardly felt the consequences of the dying down of the ethical movement. People lived on in the conditions produced. By that movement without seeing clearly that their position was no longer a tenable one and preparing to face the storm that was brewing in the relations between the nations and within the nations themselves. In this way our own age, having never taken the trouble to reflect, arrived at the opinion that civilization consists primarily in scientific, technical and artistic achievements, and that it can reach its goal without ethics, or, at any rate, with a minimum of them.

[pg 041]

Public opinion bowed down before this merely external conception of civilization because it was exclusively represented by persons whose position in society and scientific culture seemed to show them to be competent to judge in matters of the spiritual life.

* * * * *

What was the result of our giving up the ethical conception of civilization, and therewith all attempts to bring reasoned ethical ideals into effective relation with reality? It was that instead of using thought to produce ideals which fitted in with reality, we left reality without any ideals at all. Instead of discussing together the essential elements, such as population, State, Church, society, progress, which decide the character of our social development and that of mankind generally, we contented ourselves with starting from what is given by experience. Only forces and tendencies which were already at work were to be considered. Fundamental truths and convictions which ought to produce logical or ethical compulsion we would no longer acknowledge. We refused to believe that any ideas could be applicable to reality except those derived from experience. Thus ideals which had been knowingly and intentionally lowered dominated our spiritual life and the whole world.

[pg 042]

How we glorified our practical common-sense, which was to give us such power in dealing with the world! Yet we were behaving, really, like boys who give themselves up exultingly to the forces of nature and whizz down a hill on their toboggan without asking themselves whether they will be able to steer their vehicle successfully when they come to the next bend or the next unexpected obstacle.

It is only a conviction which is based upon reasoned ethical ideals that is capable of producing free activity, _i.e._, activity deliberately planned with a view to its object. In proportion as ideals taken from the workaday world are combined with it, reality influences reality. But then the human soul acts merely as an agent of debasing change.

Events which are to produce practical results within us are worked upon and moulded by our mentality. This mentality has a certain character, and on that character depends the nature of those value-judgments which rule our relation to facts.

Normally this character is to be found in the reasoned ideas which our reflection upon reality brings into existence. If these disappear there is not left a void in which "events in themselves" can affect us, but the control of our mentality passes now to the opinions and feelings which hitherto have been ruled and kept under by our reasoned ideas. When the virgin forest is cut down, brushwood [pg 043] springs up where the big trees were formerly. Whenever our great convictions are destroyed their place is taken by smaller ones which carry out in inferior fashion the functions of the former.

With the giving up of ethical ideals which accompanies our passion for reality our practical efficiency is not, therefore, improved, but diminished. It does not make the man of to-day a cool observer and calculator such as he supposes himself to be, for he is under the influence of opinions and emotions which are created in him by facts. All unconsciously he mixes with what is the work of his reason so much of what is emotional that the one spoils the other. Within this circle move the judgments and impulses of our society, whether we deal with the largest questions or the smallest. Individuals and nations alike, we deal indiscriminately with real and imaginary values, and it is just this confused medley of real and unreal, of sober thought and capacity for enthusiasm for the unmeaning, that makes the mentality of the modern man so puzzling and so dangerous.

Our sense of reality, then, means this, that, as a result of emotional and short-sighted calculations of advantage, we let one fact issue immediately in another, and so on indefinitely. As we are not consciously aiming at any definitely planned goal, our activity

may really be described as a kind of natural happening.

[pg 044]

We react to facts in the most irrational way. Without plan or foundations we build our future into the circumstances of the time and leave it exposed to the destructive effects of the chaotic jostling that goes on amongst them. “Firm ground at last”! we cry, and sink helpless in the stream of events.

* * * * *

The blindness with which we endure this fate is made worse by our belief in our historical sense, which, in this connection, is nothing else than our sense of reality prolonged backwards. We believe ourselves to be a critical generation which, thanks to its thorough knowledge of the past, is in a position to understand the direction which events are destined to take from the present to the future. We add to the ideals which have been taken from existing reality others which we borrow from history.

The achievements of historical science reached by the nineteenth century do, indeed, deserve our admiration, but it is another question whether our generation, for all its possession of an historical science, possesses a true historical sense.

Historical sense, in the full meaning of the term, implies a critical objectivity in the face of far-off and recent events alike. To keep this faculty free from the bias of opinions and interests when we are [pg 045] estimating facts is a power which even our historians do not possess. As long as they are dealing with a period so remote that it has no bearing on the present they are critical so far as the views of the school to which they belong allow it. But if the past stands in any real connection with “to-day”, we can perceive at once in their estimate the influence of their particular standpoint, rational, religious, social or economic.

It is significant that while during the last few decades the learning of our historians has, no doubt, increased, their critical objectivity has not. Previous investigators kept this ideal before their eyes in much greater purity than have those of to-day; we have gone so far that we no longer seriously make the demand that in scientific dealings with the past there shall be a suppression of all prejudices which spring from nationality or creed. It is quite common nowadays to see the greatest learning bound up with the strongest bias. In our historical literature the highest positions are occupied by works written with propagandist aims.

So little educative influence has science had on our historians that they have often espoused as passionately as anyone the opinions of their own people instead of calling the latter to a thoughtful estimate of the facts, as was their duty to their profession; they have remained nothing but men [pg 046] of learning. They have not even started on the task for which they entered the service of civilization, and the hopes of civilization, which in the middle of the nineteenth century rested on the rise of a science of history, have been as little fulfilled as those which were bound up with the demand for national States and democratic forms of government.

The generation that has been brought up by teachers such as these has naturally not much idea of an elevated or active conception of events. Accurately viewed, its characteristic feature is not so much that we understand our past better than earlier generations understood theirs, but rather that we attribute to the past an extraordinarily increased meaning for the present. Now and again we actually substitute it for the latter. It is not enough for us that what has been is present in its results in what now is; we want to have it always with us, and to feel ourselves determined by it.

In this effort to be continually experiencing our historical process of becoming, and to acknowledge it, we replace our normal relation to the past by an artificial one, and wishing to find within the past the whole of our present, we misuse it in order to deduce from it, and to legitimize by an appeal to it, our claims, our opinions, our feelings and our passions. Under the very eyes of our historical learning there springs up a manufactured history for popular use, [pg 047] in which the current national and confessional ideas are unreservedly approved and upheld, and our school history books become regular culture beds of historical lies.

The misuse of history is a necessity for us. The ideas and dispositions which rule us cannot be justified by reason; nothing is left for us but to give them foundations in history.

It is significant that we have no real interest in what is valuable in the past. Its great spiritual achievements are mechanically registered, but we do not let ourselves be touched by them. Still less do we accept them as a heritage; nothing has any value for us except what can be squared with our plans, passions, feelings, and æsthetic moods of to-day. With these we live ourselves by lies into the past, and then assert with unshaken assurance that we have our roots in it.

This is the character of the reverence we pay to history. Blinded by what we consider or declare to be past and done with, we lose all sense for what is to happen, so that of nothing can we say: “It is finished,” nothing now gets accomplished. Again and again we let what is past rise up artificially in what is present, and endow bygone facts with a persistence of being which makes wholly impossible the normal development of our peoples. Just as our sense of reality makes us lose ourselves in [pg 048] present-day events, so does our historical compel us to do the same in those of the past.

* * * * *

From these two things, our sense of reality and our historical sense, is born the nationalism to which we must refer the external catastrophe in which the decadence of our civilization finds its completion.

What is nationalism? It is an ignoble patriotism, exaggerated till it has lost all meaning, which bears the same relation to the noble and healthy kind as the fixed idea of an imbecile does to normal conviction.

How does it develop among us?

About the beginning of the nineteenth century the course of thought gave the national State its rightful position, starting for this from the axiom that it, as a natural and homogeneous organism, was better calculated than any other to make the ideal of the civilized State a working reality. In Fichte’s addresses to the German nation the nation-State is summoned to the bar of the moral reason and learns that it has to submit in all things to the latter. It gives the necessary promise and straightway receives a commission to bring the civilized State into existence. It is given emphatically to understand that it must recognize as its highest task the [pg 049] continuous and steady development of the purely human element in the nation’s life. It is to seek greatness by representing the ideas which can bring healing to the nations. Its citizens are urged to show their membership of it not through the lower, but through the higher, patriotism, that is, not to overvalue its external greatness and power, but to be careful to take for their aim “the unfolding of what is eternal and Godlike in the world,” and to see that their objects coincide with the highest aims of humanity. Thus national feeling is placed under the guardianship of reason, morality and civilization. The cult of patriotism as such is to be considered as barbarism; it does, indeed, announce itself to be such by the purposeless wars which it necessarily brings in its train.

In this way the idea of nationality was raised to the level of a valuable ideal of civilization. When civilization began to decline, its other ideals all fell also, but the idea of nationality maintained itself because it had transferred itself to the sphere of reality. It incorporated henceforward all that remained of civilization, and became the ideal which summed up all others. Here, then, we have the explanation of the mentality of our age, which concentrates all the enthusiasm of which it is capable on the idea of nationality, and believes itself to possess in that all moral and spiritual good things.

[pg 050]

But with the decay of civilization the character of the idea of nationality changed. The guardianship exercised over it by the other moral ideals to which it had hitherto been subordinate now ceased, since these were themselves on trial, and the nationalist idea began a career of independence. It asserted, of course, that it was working in the service of civilization, but it was, in truth, only an idea of reality with a halo of civilization round it, and it was guided by no ethical ideals, but only by the instincts which deal with reality.

That reason and morality shall not be allowed to contribute a word to the formation of nationalist ideas and aspirations is demanded by the mass of men to-day as a sparing of their holiest feelings.

If in earlier times the decay of civilization did not produce any such confusion in the sentiments of the various nations, this was because the idea of nationality had not then been raised in the same way to be the ideal of civilization. It was, therefore, impossible that it should insinuate itself into the place of the true ideals of civilization, and through abnormal nationalist conceptions and dispositions bring into active existence an elaborate system of uncivilization.

That in nationalism we have to do not so much with things as with the unhealthy way in which they [pg 051] are dealt with in the imagination of the crowd, is clear from its whole behaviour. It claims to be following a policy of practical results (Realpolitik); in reality it by no means represents the uncompromisingly businesslike view of all the questions of home and foreign policy, but side by side with its egoism displays a certain amount of enthusiasm. Its practical policy is an over-valuation of certain questions of territorial economic interests, an over-valuation which has been elevated to a dogma and idealized, and is now supported by popular sentiment. It fights for its demands without having established any properly thought-out calculation of their real value. In

order to be able to dispute the possession of millions of value, the modern State loaded itself with armaments costing hundreds of millions. Meaning to care for the protection and extension of its trade, it loaded the latter with imposts which imperilled its power of competing with its rivals much more than did any of the measures taken by those rivals.

Its practical politics were, therefore, in truth impracticable politics, because they allowed popular sentiment to come in, and thereby made the simplest questions insoluble. This style of politics put economic interests in the shop window, while it kept in the warehouse the ideas about greatness and conquest which belong to nationalism.

[pg 052]

Every civilized State, in order to increase its power, gathered allies wherever it could. Thus half-civilized and uncivilized races were summoned by civilized ones to fight against the civilized neighbours of the latter, and these helpers were not content with the subordinate _rôle_ which had been assigned to them. They acquired more and more influence on the course of events, till they were at last in a position to decide when the civilized nations of Europe should begin to fight each other about them. Thus has Nemesis come upon us for abandoning our wishes and betraying to the uncivilized world all that we still possessed of things that were of universal value.

It was significant of the unhealthy character of nationalism's "practical" politics that it tried in every possible way to deck itself out with a tinsel imitation of idealism. The struggle for power became one for right and civilization; the alliances for the promotion of their selfish interests which various nations made with one another against all the rest were made to appear to be friendships and spiritual affinities. As such they were dated back into the past, even though history had a great deal more to say about hereditary quarrels than about spiritual relationships.

* * * * *

[pg 053]

Finally, nationalism was not content with putting aside, in the sphere of politics generally, all attempts to bring into existence a really civilized humanity; it distorted the very idea of civilization itself and talked of national civilization.

Once there was what was known just simply as civilization, and every civilized nation strove to possess it in its purest and most fully developed form. In this respect nationality had in the idea of civilization at that time something much more original and less spoilt than it has in the same idea to-day. If, in spite of this, there was no impulse among the nations to separate the spiritual life of each from that of its neighbours, we have a proof that nationality is not in itself the strong element in the people that demanded this. Such a claim as is made to-day to have a _national civilization_ is an unhealthy phenomenon. It presupposes that the civilized peoples of to-day have lost their healthy nature, and no longer follow instincts, but theories. They percuss and sound their souls to such an extent that these are no longer capable of any natural action. They analyse and describe them so continuously that in thinking of what they ought to be they forget what they actually are. Questions of spiritual differences between races are discussed so subtly, and with such obstinacy and dogmatism, that the talk works like an obsession, and the [pg 054] peculiarities that are said to exist make their appearance like imaginary diseases.

In every department of life more and more effort is devoted to making clearly visible in the results which follow from them the emotions, the ideas, and the reasonings of the mass of the people. Any peculiarity preserved and fostered in this way shows that its natural counterpart has perished. The individual element in the personality of a people no longer, as something unconscious or half conscious, plays with varying lights on the totality of the nation's spiritual life. It becomes an artifice, a fashion, a self-advertisement, a mania. There is bred in the nation a mass of thought, the serious results of which in every department become more evident year by year. The spiritual life of some of the leading civilized nations has already, in comparison with earlier days, taken on a monotonous tone such as makes an observer feel anxious.

The unnatural character of this development shows itself not only in its results, but in the part which it allows to be played by conceit, self-importance, and self-deception. Anything valuable in a personality or a successful undertaking is attributed to some special excellence in the national character. Foreign soil is assumed to be incapable of producing the same or anything similar, and in most countries this vanity has grown to such a [pg 055] height that the greatest follies are no longer beyond its reach.

It goes without saying that there follows a serious decline in the spiritual element in the national civilization. The spirituality is, moreover, only a kind of disguise; it has in reality an avowedly materialist character. It is a distillation from all the external

achievements of the nation in question and appears in partnership with its economic and political demands. While alleged to be grounded in the national peculiarities, nationalist civilization will not, as we should normally expect, remain limited to the nation itself; it feels called upon to impose itself upon others and make them happy! Modern nations seek markets for their civilization, as they do for their manufactures!

National civilization, therefore, is matter for propaganda and for export, and the necessary publicity is secured by liberal expenditure. The necessary phrases can be obtained ready-made and need only be strung together. Thus the world has inflicted on it a competition between national civilizations, and between these civilization itself comes off badly.

The nations of Europe entered the Middle Ages side by side as the heirs of the Greco-Roman world, and lived side by side with the freest mutual intercourse through the Renaissance, the period of the [pg 056] Illuminati, and of the philosophy of more recent times. But we no longer believe that they, with their offshoots in the other continents, form an indivisible unit of civilization. If, however, in this latest age, the differences in their spiritual life have begun to stand out more distinctly, the cause of it is that the level of civilization has sunk. When the tide ebbs, shallows which separate bodies of deep water become visible; while the tide is flowing they are out of sight.

How closely the nations which form the great body of civilized humanity are still interrelated spiritually is shown by the fact that they have all side by side suffered the same decadence.

* * * * *

With our sense of reality is bound up, further, the false confidence which we have in facts. We live in an atmosphere of optimism, as if the contradictions which show themselves in the world arranged themselves automatically so as to promote well-thought-out progress, and reconciled themselves in syntheses in which the valuable parts of the thesis and the antithesis coalesced.

In justification of this optimism appeal is made, both rightly and wrongly, to Hegel. It cannot be denied that he is the spiritual father of our sense of reality; he is the first thinker who tried to be just [pg 057] to things as they exist. We have been trained by him to realize the method of progress in thesis, antithesis, and synthesis as they show themselves in the course of events. But his optimism was not a simple optimism about facts, as ours is. He lived still in the spiritual world of rationalism, and believed in the power of ethical ideas worked out by reason; that was why he believed also in the certainty of uninterrupted spiritual progress. And it was because this was something upon which he could rely that he undertook to show how it was to be seen in the successive phases of events, and at the same time how it made itself a reality in the stream of outward facts. By emphasizing, however, the progressive purpose, which he finds immanent in the course of events, so strongly that it is possible to forget the ethical-spiritual presuppositions of his belief in progress, he is preparing the way for the despiritualized optimism about reality which has for decades been misleading us. Between the facts themselves there is nothing but an endless series of contradictions.The fresh mediating fact in which they counteract each other so as to make progress possible they cannot of themselves produce. This fact can only assert itself if the contradictions resolve themselves in a reasoned view in which there are ethical ideas about the condition of things which [pg 058] it is sought to realize. These are the formative principles for the new element which is to arise out of the contradictories, and it is only in this reasoned ethical view that the latter cease to be blind, leading to no issue.

It was because we assumed the existence of principles, of progress, in the facts, that we viewed the advance of history, in which our future was being prepared, as progress in civilization, even though evolution condemned our optimism. And even now, when facts of the most terrible character cry out loudly against it, we shrink from giving up our creed. It no longer, indeed, gives us any real enlightenment, but the alternative, which bases optimism on belief in the ethical spirit, means such a revolution in our mode of thought that we find it difficult to take it into consideration.

With our reliance upon facts is bound up our reliance on organizations. The activities and the aims of our time are penetrated by a kind of obsession that if we could only succeed in perfecting or reforming in one direction or another the institutions of our public and social life, the progress demanded by civilization would begin of itself. We are, indeed, far enough from unanimity as to the plan needed for the reform of our arrangements: one section sketches out an anti-democratic plan; [pg 059] others believe that our mistake lies in the fact that democratic principles have not yet been applied consistently; others, again, see salvation only in a Socialist or Communist organization of society. But all agree in attributing our present condition, with its absence of true civilization, to a failure of our institutions; all look for the attainment of such civilization to a new organization of society; all unite in thinking that with new institutions there would arise a new spirit.

* * * * *

In this terrible confusion are entangled not only the unreflecting masses, but also many of the most earnest amongst us. The materialism of our age has reversed the relation between the spiritual and the actual. It believes that something with spiritual value can result from the working of facts. It was even expected that the war would bring us a spiritual regeneration! In reality, however, the relation between them works in the opposite direction. A spiritual element of real value can, if it is present, influence the moulding of reality so as to bring about desired results, and can thus produce facts in support of itself. All institutions and organizations have only a relative significance. With the most diverse social and political [pg 060] arrangements, the various civilized nations have all sunk to the same depth of barbarism. What we have experienced, and are still experiencing, must surely convince us that the spirit is everything and that institutions count for very little. Our institutions are a failure because the spirit of barbarism is at work in them. The best planned improvements in the organization of our society (though we are quite right in trying to secure them) cannot help us at all until we become at the same time capable of imparting a new spirit to our age.

The difficult problems with which we have to deal, even those which lie entirely in the material and economic sphere, are in the last resort only to be solved by an inner change of character. The wisest reforms in organization can only carry them a little nearer solution, never to the goal. The only conceivable way of bringing about a reconstruction of our world on new lines is first of all to become new men ourselves under the old circumstances, and then as a society in a new frame of mind so to smooth out the opposition between nations that a condition of true civilization may again become possible. Everything else is more or less wasted labour, because we are thereby building not on the spirit, but on what is merely external.

In the sphere of human events which decide the future of mankind reality consists in an inner [pg 061] conviction, not in given outward facts. Firm ground for our feet we find in reasoned ethical ideals. Are we going to draw from the spirit strength to create new conditions and turn our faces again to civilization, or are we going to continue to draw our spirit from our surroundings and go down with it to ruin? That is the fateful question with which we are confronted.

The true sense for reality is that insight which tells us that only through ethical ideas about things can we arrive at a normal relation to reality. Only so can man and society win all the power over events that they are able to use. Without that power we are, whatever we may choose to do, delivered over into bondage to them.

What is going on to-day between nations and within them throws a glaring illumination upon this truth. The history of our time is characterized by a lack of reason which has no parallel in the past. Future historians will one day analyse this history in detail, and test by means of it their learning and their freedom from prejudice. But for all future times there will be, as there is for to-day, only one explanation, viz., that we sought to live and to carry on with a civilization which had no ethical principle behind it.

[pg 062]

CHAPTER IV

THE WAY TO THE RESTORATION OF CIVILIZATION

Civilization-ideals have become powerless. Evolution and decay in the history of civilization. The reform of institutions and the reform of convictions. The individual as the sole agent of the restoration of civilization. The difficulties which beset the restoration of civilization.

The ethical conception of civilization, then, is the only one that can be justified.

But where is the road that can bring us back from barbarism to civilization? Is there such a road at all?

The unethical conception of civilization answers: “No.” To it all symptoms of decay are symptoms of old age, and civilization, just like any other natural process of growth, must after a certain period of time reach its final end. There is nothing, therefore, for us to do, so it says, but to take the causes of this as quite natural, and do our best at any rate to find interesting the unedifying phenomena of its senility, which testify to the gradual loss of the ethical character of civilization.

In the thinking then which surrenders itself to our sense of reality, optimism and pessimism are inextricably intermingled. If our optimism about [pg 063] reality is proved untenable, the optimism which thinks that continuous progress evolves itself among the facts as such, then the spirit which from above contemplates and analyses the situation turns without much concern to the mild pessimistic supposition that civilization has reached its Indian summer.

The ethical spirit cannot join in this little game of “Optimism or pessimism?” It sees the symptoms of decay as what they really are, viz., something terrible. It asks itself with a shudder what will become of the world if this dying process really goes on unchecked. The condition of civilization is a source of pain to it, for civilization is not an object which it is interesting to analyse, but the hope on which its thoughts fly out over the future existence of the race. Belief in the possibility of a renewal of civilization is an actual part of its life; that is why it can no longer quiet itself with what contents the sense of reality as it hovers between optimism and pessimism.

Those who regard the decay of civilization as something quite normal and natural console themselves with the thought that it is not civilization, but a civilization, which is falling a prey to dissolution; that there will be a new age and a new race in which there will blossom a new civilization. But that is a mistake. The earth no longer has in reserve, as it had once, gifted peoples as yet unused, [pg 064] who can relieve us and take our place in some distant future as leaders of the spiritual life. We already know all those which the earth has to dispose of. There is not one among them which is not already taking such a part in our civilization that its spiritual fate is determined by our own. All of them, the gifted and the ungifted, the distant and the near, have felt the influence of those forces of barbarism which are at work among us. All of them are, like ourselves, diseased, and only as we recover can they recover.

It is not the civilization of a race, but that of mankind, present and future alike, that we must give up as lost, if belief in a rebirth of our civilization is a vain thing.

But it need not be so given up. If the ethical is the essential element in civilization, decadence changes into renaissance as soon as ethical activities are set to work again in our convictions and in the ideas which we undertake to stamp upon reality. The attempt to bring this about is well worth making, and it should be world-wide.

It is true that the difficulties that have to be reckoned with in this undertaking are so great that only the strongest faith in the power of the ethical spirit will let us venture on it.

First among them towers up the inability of our generation to understand what is and must be. [pg 065] The men of the Renaissance and the Illuminati of the eighteenth century drew courage to desire the renewal of the world through ideas from their conviction of the absolute indefensibility of the material and spiritual conditions under which they lived. Unless with us, too, the many come to some such conviction, we must continue incapable of taking in hand this work, in which we must imitate them. But the many obstinately refuse to see things as they are, and hold with all their might to the most optimistic view of them that is possible. For this power, however, of idealizing with continually lowering ideals the reality which is felt to be ever less and less satisfying, pessimism also is partly responsible. Our generation, though so proud of its many achievements, no longer believes in the one thing which is all-essential: the spiritual advance of mankind. Having given up the expectation of this, it can put up with the present age without feeling such suffering as would compel it, for very pain, to long for a new one. What a task it will be to break the fetters of unthinking optimism and unthinking pessimism which hold us prisoners, and so to do what will pave the way for the renewal of civilization!

A second difficulty besetting the work which lies before us is that it is a piece of reconstruction. The ideas of civilization which our age needs are not new [pg 066] and strange to it. They have been in the possession of mankind already, and are to be found in many an antiquated formula. We have fundamentally nothing else to do than to restore to them the respect in which they were once held, and again regard them seriously as we bring them into relation with the reality which lies before us for treatment.

To make what is used up usable—is there a harder task? “It is an impossible one,” says history. “Never hitherto have worn-out ideas risen to new power among the peoples who have worn them out. Their disappearance has always been a final one.”

That is true. In the history of civilization we find nothing but discouragement for our task. Anyone who finds history speaking optimistically lends her a language which is not her own.

Yet from the history of the past we can infer only what has been, not what will be. Even if it proves that no single people has ever lived through the decay of its civilization and a rebirth of it, we know at once that this, which has never happened yet, must happen with us, and therefore we cannot be content to say that the reasoned ethical ideas on which civilization rests get worn out in the course of history, and console ourselves with the reflection that this is exactly in accordance with the ordinary processes of nature. We require to know why it has [pg 067] so happened hitherto, and to draw an explanation, not from the analogy of nature, but from the laws of spiritual life. We want to get into our hands the key of the secret, so that we may with it unlock the new age, the age in which the worn out becomes again unworn and the spiritual and ethical can no longer get worn out. We must study the history of

civilization otherwise than as our predecessors did, or we shall be finally lost.

Why do not thoughts which contribute to civilization retain the convincing power which they once had, and which they deserve on account of their content? Why do they lose the evidential force of their moral and rational character? Why do traditional truths cease to be realities and pass from mouth to mouth as mere phrases?

* * * * *

Is this an unavoidable fate, or is the well drying up because our thinking did not go down to the permanent level of the water?

Moreover, it is not merely that the past survives among us as something valueless; it may cast a poisonous shade over us. There are thoughts on which we have never let our minds work directly because we found them ready formulated in history. Ideas which we have inherited do not let the truth [pg 068] which is in them come out into active service, but show it through a kind of dead mask. The worn out achievements which pass over from a decadent civilization into the current of a new age often become like rejected products of metabolism, and act as poisons.

Granted that the Teutonic nations received a powerful stimulus to civilization at the Renaissance by reverting to the ideas of Greco-Roman thinkers, not less true is it that for many centuries they had been kept by that same Greco-Roman civilization in a condition of spiritual dependence which was wholly in contradiction to their native character. They took over from it decadent ideas which were for a long time a hindrance to their normal spiritual life, and thence came that strange mixture of strength and weakness which is the chief characteristic of the Middle Ages. The dangerous elements in the Greco-Roman civilization of the past still show themselves in our spiritual life. It is because Oriental and Greek conceptions which have had their day are still current among us that we bleed to death over problems which otherwise would have no existence for us. How much we suffer from the one fact that to-day and for several centuries past our thoughts about religion have been under the hereditary foreign domination of Jewish transcendentalism and Greek metaphysics, and, instead of [pg 069] being able to express themselves naturally, have suffered continual distortion!

Because ideas get worn out in this way, and in this condition hinder the thinking of later generations, there is no continuity in the spiritual progress of mankind, but only a confused succession of ups and downs. The threads get broken, or knotted, or lost, or when tied up again get tied wrongly. Hitherto it has been thought possible to interpret this up-and-down movement optimistically because it was universally held that the Renaissance and the age of the Illuminati were quite natural successors of the Greco-Roman civilization, and it was assumed further that, as a permanent result of this, renewed civilizations would spring up in the place of exhausted ones, and thus continual progress be assured. But this generalization cannot justifiably be drawn from such observations. It was because new peoples came on the scene, who had been only superficially touched by the decadent civilizations and now produced others of their own, that it was possible to see this succession of ups and downs ending in an ascent. As a matter of fact, however, our newer civilization was not in any organic connection with the Greco-Roman, even if it did take its first steps with the help of the crutches which the latter provided; it may be [pg 070] described more truly as the reaction of a healthy spirit against the worn out ideas which were thus offered to it. The essential element in the process was the contact of what was worn out with the fresh thought of young peoples.

To-day, however, all our thought is losing its power in its contact with the worn-out ideas of our expiring civilization, or—in the case of the Hindus and the Chinese—of our own and other expiring civilizations. The up-and-down movement will end, therefore, not in slow progress, but in unbroken descent—unless we can succeed in giving the worn out ideas a renewal of their youth.

* * * * *

Another great difficulty in the way of the regeneration of our civilization lies in the fact that it must be an internal process, and not an external as well, and that, therefore, there is no place for healthy co-operation between the material and the spiritual. From the Renaissance to the middle of the nineteenth century the men who carried on the work of civilization could expect help towards spiritual progress from achievements in the sphere of external organization. Demands in each of these spheres stood side by side in their programme and were pushed on simultaneously. They were convinced that while working to transform [pg 071] the institutions of public life they were producing results which would call forth the development of the new spiritual life. Success in one sphere strengthened at once the hopes and the energies that were at work in the other. They laboured for the progressive democratization of the State with the idea of thereby spreading through the world the rule of grace and justice.

We, who have lived to see the spiritual bankruptcy of all the institutions which they created, can no longer work in this way simultaneously at the reform of institutions and the revival of the spiritual element. The help which such co-operation would give is denied us. We cannot even reckon any longer on the old co-operation between knowledge and thought. Once these two were allies. The latter fought for freedom and in so doing made a road for the former, and, on the other hand, all the results attained by knowledge worked for the general good of the spiritual life in that the reign of law in nature was more and more clearly demonstrated, and the reign of prejudice was becoming continually more restricted. The alliance also strengthened the thought that the well-being of mankind must be based upon spiritual laws. Thus knowledge and thought joined in establishing the authority of reason and the rational tone of mind.

[pg 072]

To-day thought gets no help from science, and the latter stands facing it independent and unconcerned. The newest scientific knowledge may be allied with an entirely unreflecting view of the universe. It maintains that it is concerned only with the establishment of individual facts, since it is only by means of these that scientific knowledge can maintain its practical character; the co-ordination of the different branches of knowledge and the utilization of the results to form a theory of the universe are, it says, not its business. Once every man of science was also a thinker who counted for something in the general spiritual life of his generation. Our age has discovered how to divorce knowledge from thought, with the result that we have, indeed, a science which is free, but hardly any science left which reflects.

Thus we no longer have available for the renewal of our spiritual life any of the natural external helps which we used to have. We are called upon for a single kind of effort only, and have to work like men who are rebuilding the damaged foundations of a cathedral under the weight of the massive building. There is no progress in the world of phenomena to encourage us to persevere; an immense revolution has to be brought about without the aid of any collateral revolutionary activities.

* * * * *

[pg 073]

Again, the renewal of civilization is hindered by the fact that it is so exclusively the individual personality which must be looked to as the agent in the new movement.

The renewal of civilization has nothing to do with movements which bear the character of experiences of the crowd; there are never anything but reactions to external happenings. But civilization can only revive when there shall come into being in a number of individuals a new tone of mind independent of the one prevalent among the crowd and in opposition to it, a tone of mind which will gradually win influence over the collective one, and in the end determine its character. It is only an ethical movement which can rescue us from the slough of barbarism, and the ethical comes into existence only in individuals.

The final decision as to what the future of a society shall be depends not on how near its organization is to perfection, but on the degrees of worthiness in its individual members. The most important, and yet the least easily determinable, element in history is the series of unobtrusive general changes which take place in the individual dispositions of the many. These are what precede and cause the happenings, and this is why it is so difficult to understand thoroughly the men and the [pg 074] events of past times. The character and worth of individuals among the mass and the way they work themselves into membership of the whole body, receiving influences from it and giving others back, we can even to-day only partially and uncertainly understand.

One thing, however, is clear. Where the collective body works more strongly on the individual than the latter does upon it, the result is deterioration, because the noble element on which everything depends, viz., the spiritual and moral worthiness of the individual, is thereby necessarily constricted and hampered. Decay of the spiritual and moral life then sets in, which renders society incapable of understanding and solving the problems which it has to face. Thereupon, sooner or later, it is involved in catastrophe.

That is the condition in which we are now, and that is why it is the duty of individuals to rise to a higher conception of their capabilities and undertake again the function which only the individual can perform, that of producing new spiritual-ethical ideas. If this does not come about in a multitude of cases nothing can save us.

A new public opinion must be created privately and unobtrusively. The existing one is maintained by the Press, by propaganda, by organization, and by financial and other influences which are at its [pg 075] disposal. This unnatural way of spreading ideas must be opposed by the natural one, which goes from man to man and relies solely on the truth of the thoughts and the hearer's

receptiveness for new truth. Unarmed, and following the human spirit's primitive and natural fighting method, it must attack the other, which faces it, as Goliath faced David, in the mighty armour of the age.

About the struggle which must needs ensue no historical analogy can tell us much. The past has, no doubt, seen the struggle of the free-thinking individual against the fettered spirit of a whole society, but the problem has never presented itself on the scale on which it does to-day, because the fettering of the collective spirit as it is fettered to-day by modern organizations, modern unreflectiveness, and modern popular passions, is a phenomenon without precedent in history.

* * * * *

Will the man of to-day have strength to carry out what the spirit demands from him, and what the age would like to make impossible?

In the over-organized societies which in a hundred ways have him in their power, is he destined to become once more an independent personality and [pg 076] to exert influence back upon them? They will use every means to keep him in that condition of impersonality which suits them. They fear personality because the spirit and the truth, which they would like to muzzle, find in it a means of expressing themselves. And their power is, unfortunately, as great as their fear.

There is a tragic alliance between society as a whole and its economic conditions. With a grim relentlessness those conditions tend to bring up the man of to-day as a being without freedom, without self-collectedness, without independence, in short as a human being so full of deficiencies that he lacks the qualities of humanity. And they are the last things that we can change. Even if it should be granted us that the spirit should begin its work, we shall only slowly and incompletely gain power over these forces. There is, in fact, being demanded from the will that which our conditions of life refuse to allow.

And how heavy the tasks that the spirit has to take in hand! It has to create the power of understanding the truth that is really true where at present nothing is current but propagandist truth. It has to depose ignoble patriotism, and enthrone the noble kind of patriotism which aims at ends that are worthy of the whole of mankind, in circles where the hopeless issues of past and present [pg 077] political activities keep nationalist passions aglow even among those who in their hearts would fain be free from them. It has to get the fact that civilization is an interest of all men and of humanity as a whole recognized again in places where national civilization is to-day worshipped as an idol, and the notion of a humanity with a common civilization lies broken to fragments. It has to maintain our faith in the civilized State, even though our modern States, spiritually and economically ruined by the war, have no time to think about the tasks of civilization, and dare not devote their attention to anything but how to use every possible means, even those which undermine the conception of justice, to collect money with which to prolong their own existence. It has to unite us by giving us a single ideal of civilized man, and this in a world where one nation has robbed its neighbour of all faith in humanity, idealism, righteousness, reasonableness, and truthfulness, and all alike have come under the domination of powers which are plunging us ever deeper into barbarism. It has to get attention concentrated on civilization while the growing difficulty of making a living absorbs the masses more and more in material cares, and makes all other things seem to them to be mere shadows. It has to give us faith in the possibility of [pg 078] progress while the reaction of the economic on the spiritual becomes more pernicious every day and contributes to an ever growing demoralization. It has to provide us with a capacity for hope at a time when not only secular and religious institutions and associations, but the men, too, who are looked upon as leaders, continually fail us, when artists and men of learning show themselves as supporters of barbarism, and notabilities who pass for thinkers, and behave outwardly as such, are revealed, when crises come, as being nothing more than writers and members of academies.

All these hindrances stand in the path of the will to civilization. A dull despair hovers about us. How well we now understand the men of the Greco-Roman decadence, who stood before events incapable of resistance, and, leaving the world to its fate, withdrew upon their inner selves! Like them, we are bewildered by our experience of life. Like them, we hear enticing voices which say to us that the one thing which can still make life tolerable is to live for the day. We must, we are told, renounce every wish to think or hope about anything beyond our own fate. We must find rest in resignation.

The recognition that civilization is founded on some sort of theory of the universe, and can be restored only through a spiritual awakening and a will for ethical good in the mass of mankind, compels [pg 079] us to make clear to ourselves those difficulties in the way of a rebirth of civilization which ordinary reflection would overlook. But at the same time it raises us above all considerations of possibility or impossibility. If the ethical spirit provides a sufficient standing ground in the sphere of events for making civilization a reality, then we shall get civilization, provided that we return to a suitable theory of the universe and the convictions to which this properly gives birth.

The history of our decadence preaches the truth that when hope is dead the spirit becomes the deciding court of appeal, and this truth will in the future find in us a sublime and noble fulfilment.

[pg 080]

CHAPTER V

CIVILIZATION AND THEORIES OF THE UNIVERSE

The regeneration of our theory of the universe and the restoration of civilization. A reflective theory of the universe; rationalism and mysticism. The optimistic-ethical theory as a theory of civilization. The regeneration of our ideas by reflection about the meaning of life.

The greatest of all the spirit's tasks is to produce a theory of the universe (_Weltanschauung__(_*_)_), for in such a theory all the ideas, convictions and activities of an age have their roots, and it is only when we have arrived at one which is compatible with civilization that we are capable of holding the ideas and convictions which are the conditions of civilization in general.

What is meant by a theory of the universe? It is the content of the thoughts of society and the individuals which compose it about the nature and object of the world in which they live, and the position and the destiny of mankind and of individual men within it. What significance have the society in which I live and I myself in the world? What do we want to do in the world, what do we [pg 081] hope to get from it, and what is our duty to it? The answer given by the majority to these fundamental questions about existence decides what the spirit is in which they and their age live.

Is not this putting too high the value of a theory of the universe?

At present, certainly, the majority do not, as a rule, attain to any properly thought-out theory, nor do they feel the need of deriving their ideas and convictions from such a source. They are in tune, more or less, with all the tones which pervade the age in which they live.

But who are the musicians who have produced these tones? They are the personalities who have thought out theories of the universe, and drawn from them the ideas, more or less valuable, which are current amongst us to-day. In this way all thoughts, whether those of individuals or those of society, go back ultimately, in some way or other, to a theory of the universe. Every age lives in the consciousness of what has been provided for it by the thinkers under whose influence it stands.

Plato was wrong in holding that the philosophers of a State should also be its governors. Their supremacy is a different and a higher one than that which consists in taking cognizance of laws and ordinances and giving effect to official authority. [pg 082] They are the officers of the general staff who sit in the background thinking out, with more or less clearness of vision, the details of the battle which is to be fought. Those who play their part in the public eye are the subordinate officers who, for their variously sized units, convert the general directions of the staff into orders of the day: namely, that the forces will start at such and such a time, move in this or that direction, and occupy this or that point. Kant and Hegel have commanded millions who had never read a line of their writings, and who did not even know that they were obeying their orders.

Those who command, whether it be in a large or a small sphere, can only carry out what is already in the thought of the age. They do not build the instrument on which they have to play, but are merely given a seat at it. Nor do they compose the piece they have to play; it is simply put before them, and they cannot alter it; they can only reproduce it with more or less skill and success. If it is meaningless, they cannot do much to improve it, but neither, if it is good, can they damage it seriously.

To the question, then, whether it is personalities or ideas which decide the fate of an age, the answer is that the age gets its ideas from personalities. If the thinkers of a certain period produce a worthy theory of the universe, then ideas pass into currency [pg 083] which guarantee progress; if they are not capable of such production, then decadence sets in in some form or other. Every theory of the universe draws after it its own special results in history.

The fall of the Roman Empire in spite of that empire's having over it so many rulers of conspicuous ability, may be traced ultimately to the fact that ancient philosophy produced no theory of the universe with ideas which tended to that empire's preservation. With the rise of Stoicism, as the definitive answer of the philosophic thought of antiquity, the fate of the world down to the Middle Ages was decided. The idea of resignation, noble idea as it is, could not ensure progress in a world-wide empire. The efforts of its

strongest emperors were useless. The yarn with which they had to weave was rotten.

In the eighteenth century, under the rule, in most places, of insignificant rococo-sovereigns and rococo-ministers, a progressive movement began among the nations of Europe which was unique in the history of the world. Why? The thinkers of the Illuminati and of rationalism produced a worthy theory of the universe from which worthy ideas were spread among mankind.

But when history began to shape itself in accordance with these ideas, the thought which had [pg 084] produced the progress came to a halt, and we have now a generation which is squandering the precious heritage it has received from the past, and is living in a world of ruins, because it cannot complete the building which that past began. Even had our rulers and statesmen been less short-sighted than they actually were, they would not in the long run have been able to avert the catastrophe which burst upon us. Both the inner and the outer collapse of civilization were latent in the circumstances produced by the prevalent view of the universe. The rulers, small and great alike, did not [nothing but] act in accordance with the spirit of the age.

With the disappearance of the influence exerted by the _Aufklärung_, rationalism, and the serious philosophy of the early nineteenth century, the seeds were sown of the world-war to come. Then began to disappear also the ideas and convictions which would have made possible a solution on right lines of the controversies which arise between nations.

Thus the course of events brought us into a position in which we had to get along without any real theory of the universe. The collapse of philosophy and the rise and influence of scientific modes of thought made it impossible to arrive at an idealist theory which should satisfy thought. Moreover, our age is poorer in deep thinkers than perhaps any preceding one. There were a few [pg 085] strong spirits who, with varied knowledge, and with devoted efforts, offered the world some patchwork thought; there were some dazzling comets; but that was all that was granted us. Their products in the way of world theories were good enough to interest a circle of academic culture, or to delight a few believing followers, but the people as a whole were entirely untouched.

We began, therefore, to persuade ourselves that it was, after all, possible to get through without any theory of the universe. The feeling that we needed to stir ourselves up to ask questions about the world and life, and to come to a decision upon them, gradually died away. In the unreflective condition to which we had surrendered ourselves, we took, to meet the claims of our own life and the nation's life, the chance ideas provided by our feeling for reality. During more than a generation and a half we had proof enough and to spare that the theory which is the result of absence of theory is the most worthless of all, involving not only ruin to the spiritual life, but ruin universal. For where there is no general staff to think out its plan of campaign for any generation its subordinate officers lead it, as in actual warfare so in the sphere of ideas, from one profitless adventure to another.

The reconstruction of our age, then, can begin [pg 086] only with a reconstruction of a theory of the universe. There is hardly anything more urgent in its claim on us than this which seems to be so far off and abstract. Only when we have made ourselves at home again in the solid thought-building of a theory which can support a civilization, and when we take from it, all of us in co-operation, ideas which can stimulate our life and work, only then can there again arise a society which shall possess ideals with magnificent aims and be able to bring these into effective agreement with reality. It is from new ideas that we must build history anew.

For individuals as for the community, life without a theory of things is a pathological disturbance of the higher capacity for self-direction.

* * * * *

What conditions must a theory of the universe fulfil to enable it to create a civilization?

First, and defined generally, it must be the product of thought. Nothing but what is born of thought and addresses itself to thought can be a spiritual power affecting the whole of mankind. Only what has been well turned over in the thought of the many, and thus recognized as truth, possesses a natural power of conviction which will work on other minds and will continue to be effective. Only where there is a constant appeal to the need [pg 087] of a reflective view of things are all man's spiritual capacities called into activity.

Our age has a kind of artistic prejudice against a reflective theory of the universe. We are still children of the Romantic movement to a greater extent than we realize. What that movement produced in opposition to the _Aufklärung_ and to rationalism seems to us valid for all ages against any theory that would found itself solely on thought. In such a theory of the universe we can see beforehand the world dominated by a barren intellectualism, convictions governed by mere utility, and a shallow optimism, which

together throw a wet blanket over all human genius and enthusiasm.

In a great deal of the opposition which it offered to rationalism the reaction of the early nineteenth century was right. Nevertheless it remains true that it despised and distorted what was, in spite of all its imperfections, the greatest and most valuable manifestation of the spiritual life of man that the world has yet seen. Down through all circles of cultured and uncultured alike there prevailed at that time a belief in thought and a reverence for truth. For that reason alone that age stands higher than any which preceded it, and much higher than our own.

At no price must the feelings and phrases of [pg 088] Romanticism be allowed to prevent our generation from forming a clear conception of what reason really is. It is no dry intellectualism which would suppress all the manifold movements of our inner life, but the totality of all the functions of our spirit in their living action and interaction. In it our intellect and our will hold that mysterious intercourse which determines the character of our spiritual being. These fundamental ideas which it produces contain all that we can feel or imagine about our destiny and that of mankind, and give our whole being its direction and its value. The enthusiasm which comes from thought has the same relation to that which rises from the cauldron of feeling as the wind which sweeps the heights has to that which eddies about between the hills. If we venture once more to seek help from the light of reason, we shall no longer keep ourselves down at the level of a generation which has ceased to be capable of enthusiasm, but shall follow the deep and noble passion inspired by great and sublime ideals. This will so fill and expand our being that that by which we now live will seem to be merely a petty kind of excitement, and will disappear.

Rationalism is more than a movement of thought which realized itself at the end of the eighteenth and the beginning of the nineteenth centuries. It is a necessary phenomenon in all normal spiritual life. [pg 089] All real progress in the world is in the last analysis produced by rationalism.

It is true that the intellectual productions of the period which we designate historically as the rationalistic are incomplete and unsatisfactory, but the principle, which was then established, of basing our views of the universe on thought and thought alone, is valid for all time. Even if the tree's earliest fruit did not ripen perfectly, the tree itself remains, nevertheless, the tree of life for the life of our spirit.

All the movements that have claimed to take the place of rationalism stand far below it in the matter of achievement. From speculative thought, from history, from feeling, from æsthetics, from science, they tried to construct a theory of the universe, grubbing at haphazard in the world around them instead of excavating scientifically. Rationalism alone chose the right place for its digging, and dug systematically, according to plan. If it found only metal of small value, that was because, with the means at its disposal, it could not go deep enough. Impoverished and ruined as we are because we sought as mere adventurers, we must make up our minds to sink another shaft in the ground where rationalism worked, and to go down through all the strata to see whether we cannot find the gold which must certainly be there.

[pg 090]

To think out to the end a theory of the universe which has been produced by thought—that is the only possible way of finding our bearings amid the confusion of the world of thought to-day.

Philosophical, historical, and scientific questions with which it was not capable of dealing overwhelmed the earlier rationalism like an avalanche, and buried it in the middle of its journey. The new rational theory of the universe must work its way out of this chaos. Leaving itself freely open to the whole influence of the world of fact, it must explore every path offered by reflection and knowledge in its effort to reach the ultimate meaning of being and life, and to see whether it can solve some of the riddles which they present.

The ultimate knowledge, in which man recognizes his own being as a part of the All, belongs, they say, to the realm of mysticism, by which is meant that he does not reach it by the method of ordinary reflection, but somehow or other lives himself into it.

But why assume that the road of thought must suddenly stop at the frontier of mysticism? It is true that pure reason has hitherto called a halt whenever it came into this neighbourhood, for it was unwilling to go beyond the point at which it could still exhibit everything as part of a smooth, logical plan. Mysticism, on its side, always depreciated [pg 091] pure reason as much as it could, to prevent at all costs the idea from gaining currency that it was in any way bound to give an account to reason. And yet, although they refuse to recognize each other, the two belong to each other.

It is in reason that intellect and will, which in our nature are mysteriously bound up together, seek to come to a mutual understanding. The ultimate knowledge that we strive to acquire is knowledge of life, which intellect looks at from without, will from within. Since life is the ultimate object of knowledge, our ultimate knowledge is necessarily our thinking experience of life, but this does not lie outside the sphere of reason, but within reason itself. Only when the will has thought out its relation to the intellect, has come, as far as it can, into line with it, has penetrated it, and in it become logical, is it in a position to comprehend itself, so far as its nature allows this, as a part of the universal will-to-live and a part of being in general. If it merely leaves the intellect on one side, it loses itself in confused imaginings, while the intellect, which, like the rationalism of the past, will not allow that in order to understand life it must finally lose itself in thinking experience, renounces all hope of constructing a deep and firmly based theory of the universe.

[pg 092]

Thus reflection, when pursued to the end, lead somewhere and somehow to a living mysticism which is for all men everywhere a necessary element of thought.

Doubts whether the mass of men can ever attain to that level of reflection about themselves and the world which is demanded by a reflective theory of the universe, are quite justifiable if the man of to-day is taken as an example of the race. But he, with his diminished need of thought, is a pathological phenomenon.

In reality there is given in the mental endowment of the average man a capacity for thought which to the individual makes the creation of a reflective theory of things of his own not only possible, but under normal conditions even a necessity. The great movements of illumination in ancient and modern times help to maintain the confident belief that there is in the mass of mankind a power of thought on fundamentals which can be roused to activity. This belief is strengthened by observation of mankind and intercourse with the young. A fundamental impulse to reflect about the universe stirs us during those years in which we begin to think independently. Later on we let it languish, even though feeling clearly that we thereby impoverish ourselves and become less capable of what is good. We are like springs of water which no longer run [pg 093] because they have not been watched and have gradually become choked with rubbish.

More than any other age has our own neglected to watch the thousand springs of thought; hence the drought in which we are pining. But if we only go on to remove the rubbish which conceals the water, the sands will be irrigated again, and life will spring up where hitherto there has been only a desert.

Certainly there are guides and the guided in the department of world-theories, as in others. So far the independence of the mass of men remains a relative one. The question is only whether the influence of the guides leads to dependence or independence. The latter brings with it a development in the direction of truthfulness; the former means the death of that virtue.

Every being who calls himself a man is meant to develop into a real personality within a reflective theory of the universe which he has created for himself.

* * * * *

But of what character must the theory be if ideas and convictions about civilization are to be based on it?

That theory of the universe is optimistic which [pg 094] gives existence the preference as against non-existence and thus affirms life as something possessing value in itself. From this attitude to the universe and to life results the impulse to raise existence, in so far as our influence can affect it, to its highest level of value. Thence originates activity directed to the improvement of the living conditions of individuals, of society, of nations and of humanity, from which spring the external achievements of civilization, the lordship of spirit over the powers of nature, and the higher social organization.

Ethics is the activity of man directed to secure the inner perfection of his own personality. In itself it is quite independent of whether the theory of the universe is pessimistic or optimistic. But its sphere of action is contracted or widened according as it appears in connection with a theory of the first or the second type.

In the determinist-pessimistic theory of the universe, as we have it in the thought of the Br■hmans or of Schopenhauer, ethics has nothing whatever to do with the objective world. It aims solely at securing the self-perfection of the individual as this comes to pass in inner freedom and disconnection from the world and the spirit of the world.

But the scope of ethics is extended in proportion [pg 095] as it develops and strengthens a connection with a theory of the universe which is affirmative toward the world and life. Its aim is now the inner perfection of the individual and at the same time the direction of his activity so as to take effect on other men and on the objective world. It is true that in face of the objective world and its spirit ethics no longer holds itself up to man as an aim in itself. By its means man is to become capable of acting among men and in the world as a higher and purer force, and thus to do his part towards the actualization of the ideal of general progress.

Thus the optimistic-ethical theory of the universe works in partnership with ethics to produce civilization. Neither is capable of doing so by itself. Optimism supplies confidence that the world-process has somehow or other a spiritual-sensible aim, and that the improvement of the general relations of the world and of society promotes the spiritual-moral perfection of the individual. From ethics is derived ability to develop the purposive state of mind necessary to produce action on the world and society and to cause the co-operation of all our achievements to secure the spiritual and moral perfection of the individual which is the final end of civilization.

Once we have recognized that the energies which spring out of a theory of the universe, and impel us to [pg 096] create a civilization, are rooted in the ethical and the optimistic, we get light on the question why and how our ideals of civilization got worn out. This question is not to be answered by good or bad analogies from nature. The decisive answer is that they got worn out because we had not succeeded in establishing the ethical and optimistic elements on a sufficiently firm foundation.

If we should analyse the process in which the ideas and convictions that produce civilization reveal themselves, it would be found that whenever an advance has been registered, either the optimist or the ethical element in the theory of the universe has proved more attractive than usual, and has had as its consequence a progressive development. When civilization is decaying there is the same chain of causation, but it works negatively. The building is damaged or falls in because the optimist element or the ethical, or both, give way like a weak foundation. No amount of inquiry will give any other reason for the changes. All imaginable ideas and convictions of that character spring from optimism and the ethical impulse. If these two pillars are strong enough, we need have no fears about the building.

The future of civilization depends, therefore, on whether it is possible for thought to reach a theory of the universe which will have a more secure and [pg 097] fundamental hold on optimism and the ethical impulse than its predecessors have had.

* * * * *

We Westerners dream of a theory of the universe which corresponds to our impulse to action and at the same time justifies it. We have not been able to formulate such a theory definitely. At present we are in the state of possessing merely an impulse without any definite orientation. The spirit of the age drives us into action without allowing us to attain any clear view of the objective world and of life. It claims our toil inexorably in the service of this or that end, this or that achievement. It keeps us in a sort of intoxication of activity so that we may never have time to reflect and to ask ourselves what this restless sacrifice of ourselves to ends and achievements really has to do with the meaning of the world and of our lives. And so we wander hither and thither in the gathering dusk formed by lack of any definite theory of the universe like homeless, drunken mercenaries, and enlist indifferently in the service of the common and the great without distinguishing between them. And the more hopeless becomes the condition of the world in which this adventurous impulse to action and progress ranges to and fro, the more bewildered [pg 098] becomes our whole conception of things and the more purposeless and irrational the doings of those who have enlisted under the banner of such an impulse.

How little reflection is present in the Western impulse to action becomes evident when this tries to square its ideas with those of the Far East. For thought in the Far East has been constantly occupied in its search for the meaning of life, and forces us to consider the problem of the meaning of our own restlessness, the problem which we Westerners burke so persistently. We are utterly at a loss when we contemplate the ideas which are presented to us in Indian thought. We turn away from the intellectual presumption which we find there. We are conscious of the unsatisfying and incomplete elements in the ideal of cessation from action. We feel instinctively that the will-to-progress is justified not only in its aspect as directed to the spiritual perfection of personality, but also in that which looks towards the general and material.

For ourselves we dare to allege that we adventurers, who take up an affirmative attitude toward the world and toward life, however great and even ghastly our mistakes may be, can yet show not only greater material, but also greater spiritual and ethical, contributions than can those who lie under the ban of a theory of the universe characterized by cessation from action.

[pg 099]

And yet, all the same, we cannot feel ourselves completely justified in the face of these strange Eastern theories. They have in them something full of nobility which retains its hold on us, even fascinates us. This tinge of nobility comes from the fact that these convictions are born of a search for a theory of the universe and for the meaning of life. With us, on the other hand, activist instincts and impulses take the place of a theory of the universe. We have no theory affirming the world and life to oppose to the negative theory of these thinkers, no thought which has found a basis for an optimistic conception of existence to oppose to this other, which has arrived at a pessimistic conception.

The reawakening of the Western spirit must thus begin by our people, educated and simple alike, becoming conscious of their lack of a theory of the universe and feeling the horror of their consequent position. We can no longer be satisfied to make shift with substitutes for such a theory. What is the basis of the will-to-activity and progress which impels both to great actions and to terrible deeds, and which tries to keep us from reflection? We must bend all our energies to the solution of this problem.

There is only one way in which we can hope to emerge from the meaningless state in which we are [pg 100] now held captive into one informed with meaning. Each one of us must turn to contemplate his own being, and we must all give ourselves to co-operative reflection so as to discover how our will to action and to progress may be intellectually based on the way in which we interpret our own lives and the life around us, and the meaning which we give to these.

The great revision of the convictions and ideals in which and for which we live will only take place when, by constantly proclaiming them, we have given currency among our contemporaries to ideas and thoughts other and better than those by which they are dominated at the moment. Only thus will the many come to reflect about the meaning of life and to reorientate, revise and make over again their ideals of action and of progress, asking themselves whether these have a meaning in accord with that which we attribute to our life itself. This personal reflection about final and elemental things is the one and only reliable way of measuring values. My willing and doing have real meaning and value only in proportion as the aims which action sets before itself can be justified as being in direct accord with my interpretation of my own and of other life. All else, however much it may pass current as approved by tradition, usage, and public opinion, is vain and dangerous.

It seems, indeed, a matter for scorn and derision [pg 101] that we should urge men to anything so remote as a return to reflection about the meaning of life at a time when the sufferings and the follies of the nations have become so intense and so extended, when unemployment and poverty and starvation are rife, when power is being dissipated on all sides in the most shameless and senseless way, and when organized human life is dislocated in every direction. But only when the general population begins to reflect in this way will forces come into being which will be able to effect something to counterbalance all this ruin and misery. Whatever other measures it is attempted to carry out will have doubtful and altogether inadequate results.

When in the spring the withered grey of the pastures gives place to green, this is due to the millions of young shoots which sprout up freshly from the old roots. In like manner the revival of thought which is essential for our time can only come through a transformation of the opinions and ideals of the many brought about by individual and universal reflection about the meaning of life and of the world.

But are we sure of being able to think out that affirmation of the world and of life, which is such a powerful impulse in us, into a theory of the world and of life from which a stream of energy productive [pg 102] of intelligible life and action may convincingly and constantly proceed? How are we to succeed in doing what the spirit of the Western world during past generations has in vain toiled to accomplish?

Even if thought, once more awakened, should only attain to an incomplete and unsatisfying theory of the universe, yet this, as the truth to which we have ourselves worked through, would be of more value than a complete lack of any theory at all, or, alternatively, than any sort of authoritative theory to which, neglecting the demands of true thought, we cling on account of its supposed intrinsic value without having any real and thorough belief in it.

The beginning of all spiritual life of any real value is courageous faith in truth and open confession of the same. The most profound religious experience, too, is not alien to thought, but must be capable of derivation from this if it is to be given a true and deep basis. Mere reflection about the meaning of life has already value in itself. If such reflection should again come into being amongst us, the ideals, born of vanity and of suffering, which now flourish in rank profusion like evil weeds among the convictions of the generality of people, would infallibly wither away and die. How much would already be accomplished towards our salvation from our present

circumstances if only we would all give up three minutes every evening to gazing up into the infinite [pg 103] world of the starry heavens and meditating on it, or if in taking part in a funeral procession we would reflect on the enigma of life and death, instead of engaging in thoughtless conversation as we follow behind the coffin! The ideals, born of folly and suffering, of those who make public opinion and direct public events, would have no more power over men if they once began to reflect about eternity and mortality, existence and dissolution, and thus learnt to distinguish between true and false standards, between those which possess real value and those which do not. The old-time rabbis used to teach that the kingdom of God would come if only the whole of Israel would really keep a single Sabbath simultaneously! How much more is it true that the injustice and violence and untruth, which are now bringing so much disaster on the human race, would lose their power if only a single real trace of reflection about the meaning of the world and of life should appear amongst us!

But is there not a danger in challenging men with this question about the meaning of life and in demanding that our impulse to action should justify and clarify itself in such reflection as that of which we have spoken? Shall we not lose, in acceding to this demand, some irreplaceable element of naïve enthusiasm?

[pg 104]

We need not thus be anxious as to how strong or how weak our impulse to action will prove to be when it shall have arrived, as the result of intellectual reflection, at an interpretation of life. Only that has real meaning for life which is given as an element of our interpretation of life. It is not the quantity, but the quality, of activity that really matters. What is needed is that our will-to-action should become conscious of itself and should cease to work blindly.

But perhaps, it may be objected, we shall end in the resignation of agnosticism, and shall be obliged to confess that we cannot discover any meaning in the universe or in life.

If thought is to set out on its journey unhampered, it must be prepared for anything, even for arrival at intellectual agnosticism. But even if our will-to-action is destined to wrestle endlessly and unavailingly with an agnostic view of the universe and of life, still this painful disenchantment is better for it than persistent refusal to think out its position at all. For this disenchantment does, at any rate, mean that we are clear as to what we are doing.

There is, however, no necessity whatever for such an attitude of resignation. We feel that a position of affirmation regarding the world and life is something which is in itself both necessary and valuable. Therefore it is at least likely that a foundation can be [pg 105] found for it in thought. Since it is an innate element of our will-to-live, it must be possible to comprehend it as a necessary corollary to our interpretation of life. Perhaps we shall have to look elsewhere than we have done hitherto for the real basis of that theory of the universe which carries with it affirmation of the world and of life. Previous thought imagined that it could deduce the meaning of life from its interpretation of the universe. It may be that we shall be obliged to resign ourselves to abandon the problem of the interpretation of the universe and to find the meaning of our life in the will-to-live as this exists in ourselves.

The ways along which we have to struggle toward the goal may be veiled in darkness, yet the direction in which we must travel is clear. We must reflect together about the meaning of life; we must strive together to attain to a theory of the universe affirmative of the world and of life, in which the impulse to action which we experience as a necessary and valuable element of our being may find justification, orientation, clarity and depth, may receive a fresh access of moral strength, and be retempered, and thus become capable of formulating, and of acting on, definite ideals of civilization, inspired by the spirit of true humanitarianism.

FOOTNOTES

* _Weltanschauung_. Translated ‘theory of the universe’ throughout the first part and elsewhere in this preface.

* Translated “world-view” throughout the second part of these Lectures.

TRANSCRIBER’S NOTES

The formatting of both the .htm and .txt files followed that of two similar books, The Quest of the Historical Jesus and The Mystery of the Kingdom of God, already in Project Gutenberg.

In the .txt version I have used utf8 encoding and the following markers:

1. italic text surrounded by _ 2. footnote references in the form _(_number_)_

I have included page numbers in the format [pg xxx] for both .htm and .txt.

I made several hyphenation choices, mostly forced by de-hyphenation at the ends of lines:

1. world-theory 2. overcoming 3. self-regarding 4. never-concentrated 5. over-organization 6. over-valuation 7. self-importance 8. rococo-ministers 9. non-existence

In addition, on page 5 of the .pdf file on Internet Archive, the display of this page was corrupted in my copy. As pointed out by an editor, this has been corrected in the current version at Internet Archive.

On page 84 the word “not” in the sentence:

“The rulers, small and great alike, did not act in accordance with the spirit of the age.”

was changed to “[nothing but]”. The original German is:

“Die kleinen und die großen Regierenden taten nichts anderes, als daß sie im Geiste der Zeit handelten.”

Google Translate (4/25/2025) renders this as:

“The small and the big rulers did nothing other than act in the spirit of the times.”

The printed sentence in the book is either a typo or a mis-translation. It does not fit the sense of the author who means that the rulers themselves are not to blame for the collapse of civilization but rather it is the fault of the “spirit of the age”.

BY THE AUTHOR

PREFACE

The lack of a modern and well-illustrated book on the structure of the principal domestic animals has been acutely felt for a long time by teachers, students, and practitioners of veterinary medicine. The work here offered is the expression of a desire to close this gap in our literature.

The study of frozen sections and of material which has been hardened by intravascular injection of formalin has profoundly modified our views concerning the natural shape of many of the viscera and has rendered possible much greater precision in topographic statements. The experience of the author during the last ten years, in which almost all of the material used for dissection and for frozen sections in the anatomical laboratory of this University has been hardened with formalin, has demonstrated that many of the current descriptions of the organs in animals contain the same sort of errors as those which prevailed in regard to similar structures in man previous to the adoption of modern methods of preparation.

While the method of treatment of the subject is essentially systematic, topography is not by any means neglected either in text or illustrations; it is hoped that this will render the book of value to the student in his clinical courses and to the practitioner. Embryological and histological data have been almost entirely excluded, since it was desired to offer a text-book of convenient size for the student and a work of ready reference for the practitioner. It is believed that the use of black type for the names of important structures and of small print for certain details or matter of secondary importance will prove useful in this respect.

Veterinary anatomical nomenclature is at present quite chaotic in English-speaking countries. In this work an attempt is made to eliminate some terms which do not appear to the author to fulfil any useful purpose, and others which are clearly erroneous or

otherwise undesirable. In many cases the terms agreed upon by the Congresses at Baden and Stuttgart are adopted either in the original Latin or in anglicized form; otherwise these terms are added in parenthesis. The author favors the substantial adoption of this terminology, but considered it desirable to offer a sort of transitional stage at present.

The original illustrations are chiefly reproductions of photographs, many of which were taken by Mr. F. H. Haskett. The preparation of the pictures for reproduction was carried out by Messrs. J. V. Alteneder and W. J. Norris. The author takes pleasure in expressing his appreciation of the care and skill exercised by these gentlemen in this often difficult task.

The author is under great obligation to Professors Ellenberger and Baum in Dresden, to Professor Schmaltz in Berlin, and to their publishers for permission to use or to copy figures from their most excellent works. Their generosity in this matter has made it possible to supply this text with a larger number of high-class illustrations than is to be found in any other. A few figures have been taken from other sources, and proper credit has been given in each case.

For checking over certain data and for assistance in the correction of the proofs the author is much indebted to his associate, Dr. F. B. Hadley.

The author desires to express his high appreciation of the determination and constant effort of the publishers to do all in their power to render the book worthy of favorable reception by the profession for whom it is intended.

INDEX 783

VETERINARY ANATOMY

INTRODUCTION

=Anatomy= is the branch of biological science which deals with the form and structure of organisms, both animal and vegetal. It is therefore in close correlation with physiology, which treats of the functions of the body.

Etymologically the word “anatomy” signifies the cutting apart or disassociating of parts of the body. In the earlier phases of its development anatomy was necessarily a purely descriptive science, based on such observations as were possible with the unaided eye and simple dissecting instruments—the scalpel, forceps, and the like. At this time, therefore, the term adequately expressed the nature of the subject. But as the scope of the science extended and the body of anatomical knowledge grew, subdivisions became necessary and new terms were introduced to designate special fields and methods of work. With the introduction of the microscope and its accessories it became possible to study the finer details of structure and minute organisms hitherto unknown, and this field of inquiry rapidly developed into the science of =microscopic anatomy= or =histology= as conventionally distinguished from =gross= or =macroscopic anatomy=. In the same way the study of the changes which organisms undergo during their development soon attained sufficient importance to be regarded on practical grounds as a separate branch known as =embryology=.

This term is usually limited in its application to the earlier phases of development during which the tissues and organs are formed. The term =ontogeny= is used to designate the entire development of the individual. The ancestral history or =phylogeny= of the species is constituted by the evolutionary changes which it has undergone as disclosed by the geological record.

=Comparative anatomy= is the description and comparison of the structure of animals, and forms the basis for their classification. By this means—including extinct forms in the scope of inquiry—it has been possible to show the genetic relationship of various groups of animals and to elucidate the significance of many facts of structure which are otherwise quite obscure. The deductions concerning the general laws of form and structure derived from comparative anatomical studies constitute the science of =morphology= or =philosophical anatomy=. The morphologist, however, deals only with such anatomical details as are necessary to form a basis for his generalizations. The anatomical knowledge required in the practice of medicine and surgery is evidently of a different character and must include many details which are of no particular interest to the morphologist.

=Special anatomy= is the description of the structure of a single type or species, _e. g._, anthropotomy, hippotomy.

=Veterinary anatomy= is the branch which deals with the form and structure of the principal domesticated animals. It is usually pursued with regard to professional requirements, and is therefore largely descriptive in character. As a matter of convenience the horse is generally selected as the type to be studied in detail and to form a basis for comparison of the more essential differential characters in the other animals.

Two chief methods of study are employed—the =systematic= and the =topographic=. In the former the body is regarded as consisting of systems of organs or apparatus which are similar in origin and structure and are associated in the performance of certain functions. The divisions of =systematic anatomy= are:

1. Osteology

2. Arthrology

3. Myology

4. Splanchnology

(1) Digestive System

(2) Respiratory System

(3) Urogenital System

(_a_) Urinary Organs

(_b_) Genital Organs

5. Angiology

6. Neurology

7. Æsthesiology

(1) Sense Organs

(2) Common Integument.

The term =topographic anatomy= designates the methods by which the relative positions of the various parts of the body are accurately determined. It presupposes a fair working knowledge of systematic anatomy.

=Descriptive Terms.=—In order to indicate precisely the position and direction of parts of the body, certain descriptive terms are employed, and must be understood at the outset. In the explanation of these terms it is assumed here that they apply to a quadruped such as the horse in the ordinary standing position. The surface directed toward the plane of support (the ground) is termed =inferior= or =ventral=, and the opposite surface is =superior= or =dorsal=; the relations of parts in this direction are named accordingly. The longitudinal =median plane= divides the body into similar halves. A structure or surface which is nearer than another to the median plane is =internal= or =medial= to it, and an object or surface which is further than another from the median

plane is =external= or =lateral= to it. Planes parallel to the median plane are =sagittal=. =Transverse= or =segmental= planes cut the long axis of the body perpendicular to the median plane, or an organ or limb at right angles to its long axis. A =frontal= plane is perpendicular to the median and transverse planes. The head end of the body is termed =anterior=, =cephalic=, or =cranial=; and the tail end =posterior= or =caudal=; relations of structures with regard to the longitudinal axis of the body are designated accordingly. Certain terms are used in a special sense as applied to the limbs. =Proximal= and =distal= express relative distances of parts from the axis of the body. The anterior face of the thoracic limb from the elbow downward is also termed =dorsal=, and the opposite face =volar=. In the corresponding part of the pelvic limb the terms are =dorsal= and =plantar= respectively. In the same regions =radial= and =ulnar= (thoracic limb), =tibial= and =fibular= (pelvic limb), may be used to designate that side of the extremity on which the corresponding bone is situated; they are therefore equivalent respectively to internal or medial and external or lateral in the animals with which we are concerned.

It is evidently advantageous to employ terms which are as far as possible independent of the position of the body in space and capable of general application, _e. g._, dorsal, ventral, proximal, etc. It is also desirable that the terms internal and external be reserved to indicate relations of depth in cavities or organs, and medial and lateral to designate relations to the median plane. Such terms are coming into more extensive use in human and veterinary anatomy, but the older nomenclature is very firmly established and cannot well be discarded at once and entirely.

OSTEOLOGY

THE SKELETON

The term =skeleton= is applied to the framework of hard structures which supports and protects the soft tissues of animals. In the descriptive anatomy of the higher animals it is usually restricted to the bones and cartilages, although the ligaments which bind these together might well be included.

In zoölogy the term is used in a much more comprehensive sense, and includes all the harder supporting and protecting structures. When the latter are situated externally, they form an =exoskeleton=, derived from the ectoderm. Examples of this are the shells and chitinous coverings of many invertebrates, the scales of fishes, the shields of turtles, and the feathers, hair, and hoofs of the higher vertebrates. The =endoskeleton= (with which we have to deal at present) is embedded in the soft tissues. It is derived chiefly from the mesoderm, but includes the notochord or primitive axial skeleton, which is of entodermal origin.

The skeleton may be divided primarily into three parts: (1) axial; (2) appendicular; (3) splanchnic.

The =axial skeleton= comprises the vertebral column, ribs, sternum, and skull.

The =appendicular skeleton= includes the bones of the limbs.

The =splanchnic skeleton= consists of certain bones developed in the substance of some of the viscera or soft organs, _e. g._, the os penis of the dog and the os cordis of the ox.

The =number= of the bones of the skeleton of an animal varies with age, owing to the fusion during growth of skeletal elements which are separate in the fœtus or the young subject. Even in adults of the same species numerical variations occur, _e. g._, the tarsus of the horse may consist of six or seven bones, and the carpus of seven or eight; in all the domestic mammals the number of coccygeal vertebræ varies considerably.

The bones are commonly divided into four classes according to their shape and function.

(1) =Long bones= (Ossa longa) are typically of elongated cylindrical form with enlarged extremities. They occur in the limbs, where they act as supporting columns and as levers. The cylindrical part, termed the shaft or body (Corpus), is tubular, and incloses the =medullary cavity=, which contains the medulla or marrow.

(2) =Flat bones= (Ossa plana) are expanded in two directions. They furnish sufficient area for the attachment of muscles and afford protection to the organs which they cover.

(3) =Short bones= (Ossa brevia), such as those of the carpus and tarsus, present somewhat similar dimensions in length, breadth, and thickness. Their chief function appears to be that of diffusing concussion. Sesamoid bones, which are developed in the

capsules of some joints or in tendons, may be included in this group. They diminish friction or change the direction of tendons.

(4) =Irregular bones.= This group would include bones of irregular shape, such as the vertebræ and the bones of the cranial base; they are median and unpaired. Their functions are various and not so clearly specialized as those of the preceding classes.

This classification is not entirely satisfactory; some bones, _e. g._, the ribs, are not clearly provided for, and others might be variously placed.

STRUCTURE OF BONES[1]

Bones consist chiefly of =bone tissue=, but considered as organs they present also an enveloping membrane, termed the =periosteum=, the =medulla= or =marrow=, =vessels=, and =nerves=.

The architecture of bone can be studied best by means of longitudinal and cross-sections. These show that the bone consists of an external shell of dense =compact substance=, within which is the more loosely arranged =spongy substance=. In typical long bones the shaft is hollowed to form the =medullary cavity= (Cavum medullare).

[Illustration:

FIG. 1.—FRONTAL SECTION OF LARGE METATARSAL BONE OF HORSE, POSTERIOR PART.]

[Illustration:

FIG. 2.—SAGITTAL SECTION OF LARGE METATARSAL BONE OF HORSE.

_S.C._, Compact substance; _S.s._, spongy substance; _C.m._, medullary cavity; _F.n._, nutrient foramen. Note the greater thickness of the compact substance of the inner and anterior parts of the shaft.]

The =compact substance= (Substantia compacta) differs greatly in thickness in various situations, in conformity with the stresses and strains to which the bone is subjected. In the long bones it is thickest in the middle part of the shaft and thins out toward the extremities. On the latter the layer is very thin, and is especially dense and smooth on joint surfaces.

The =spongy substance= (Substantia spongiosa) consists of delicate bony plates and spicules which run in various directions and intercross. These plates are definitely arranged with regard to mechanical requirements, so that systems of pressure and tension plates can be recognized, in conformity with the lines of pressure and the pull of tendons and ligaments respectively. The intervals (marrow spaces) between the plates are occupied by marrow. The spongy substance forms the bulk of short bones and of the extremities of long bones; in the latter it is not confined to the ends, but extends a variable distance along the shaft also. Some bones (Ossa pneumatica) contain =air-spaces= or =sinuses= within the compact substance instead of spongy bone and marrow. In certain situations the two compact layers of flat bones are not separated by spongy bone, but fuse with each other; in some cases of this kind the bone is so thin as to be translucent, or may even undergo absorption, producing an actual deficiency.

The flat bones of the cranial vault and sides are composed of an outer layer of ordinary compact substance, an inner layer of very dense bone, the =tabula vitrea=, and between these a variable amount of spongy bone, here termed =diploë=.

The =periosteum= is the membrane which invests the outer surface of bone, except where it is covered with cartilage. It consists of an outer protective fibrous layer, and an inner cellular osteogenic layer. During active growth the osteogenic layer is well developed, but later it becomes much reduced. The fibrous layer varies much in thickness, being in general thickest in exposed situations. The adhesion of the periosteum to the bone also differs greatly in various places; it is usually very thin and easily detached where it is thickly covered with muscular tissue which has little or no attachment. The degree of vascularity conforms to the activity of the periosteum.

The =marrow= (Medulla ossium) occupies the interstices of the spongy bone and the medullary cavity of the long bones. There are two varieties in the adult—red and yellow. In the young subject there is only =red marrow= (Medulla ossium rubra), but later this is replaced in the medullary cavity by =yellow marrow= (Medulla ossium flava). The red marrow contains several types of characteristic cells and is a blood-forming substance, while the yellow is practically ordinary adipose tissue.

Since yellow marrow is formed by regressive changes in red marrow, including fatty infiltration and degeneration of the characteristic cells, we find transitional forms or stages in the process. In aged or badly nourished subjects the marrow may

undergo gelatinous degeneration, resulting in the formation of gelatinous marrow.

=Vessels and Nerves.=—It is customary to recognize two sets of =arteries=—the =periosteal= and the =medullary=. The former ramify in the periosteum and give off innumerable small branches which enter minute openings (Volkmann's canals) on the surface and reach the Haversian canals of the compact substance. Other branches enter the extremities of the long bones and supply the spongy bone and marrow in them. In the case of the larger bones—and especially the long bones—the large =medullary= or =nutrient artery= enters at the so-called =nutrient foramen= (Foramen nutricium), passes in a canal (Canalis nutricius) through the compact substance, and ramifies in the marrow; its branches anastomose with the central branches of the periosteal set. The larger =veins= of the spongy bone do not, as a rule, accompany the arteries, but emerge chiefly near the articular surfaces. Within the bone they are destitute of valves.

The =lymph vessels= form perivascular channels in the periosteum and the Haversian canals of the compact substance. Lymph-spaces exist at the periphery of the marrow.

The =nerves= appear to be distributed chiefly to the blood-vessels. Special nerve-endings (Vater-Pacini corpuscles) in the periosteum are to be regarded as sensory, and probably are concerned in mediating the muscle sense (Kopsch).

DEVELOPMENT AND GROWTH OF BONE[2]

The primitive embryonal skeleton consists of cartilage and fibrous tissue, in which the bones develop. The process is termed =ossification= or =osteogenesis=, and is effected essentially by bone-producing cells, called =osteoblasts=. It is customary, therefore, to designate as =membrane bones= those which are developed in fibrous tissue, and as =cartilage bones= those which are preformed in cartilage. The principal membrane bones are those of the roof and sides of the cranium and most of the bones of the face. The cartilage bones comprise, therefore, most of the skeleton. Correspondingly we distinguish =intramembranous= and =endochondral ossification=.

[Illustration:

FIG. 3.—LEFT FEMUR OF YOUNG PIG, EXTERNAL VIEW, TO SHOW DIVISION OF A LONG BONE INTO SHAFT (_s_) AND EXTREMITIES.

Proximal extremity consists of two parts, head (_h_) and trochanter major (_t. m._), which have separate centers of ossification. Distal extremity consists of trochlea (_t_) and condyles (_c_); _e.l._, epiphyseal cartilages; _s.f._, supracondyloid fossa.]

In intramembranous development the process begins at a definite =center of ossification= where the cells (osteoblasts) surround themselves with a deposit of bone. The process extends from this center to the periphery of the future bone, thus producing a network of bony trabeculæ. The trabeculæ rapidly thicken and coalesce, forming a bony plate which is separated from the adjacent bones by persistent fibrous tissue. The superficial part of the original tissue becomes periosteum, and on the deep face of this successive layers of periosteal bone are formed by osteoblasts until the bone attains its definitive thickness.

In endochondral ossification the process is fundamentally the same, but not quite so simple. Osteoblasts emigrate from the deep face of the perichondrium or primitive periosteum into the cartilage and cause calcification of the matrix or ground-substance of the latter. Vessels extend into the calcifying area, the cartilage cells shrink and disappear, forming primary marrow cavities which are occupied by processes of the osteogenic tissue. There is thus formed a sort of scaffolding of calcareous trabeculæ on which the bone is constructed by the osteoblasts. At the same time perichondral bone is formed by the osteoblasts of the primitive periosteum. The calcified cartilage is broken down and absorbed through the agency of large cells called =osteoclasts=, and is replaced by bone deposited by the osteoblasts. The osteoclasts also cause absorption of the primitive bone, producing the marrow cavities; thus in the case of the long bones the primitive central spongy bone is largely absorbed to form the medullary cavity of the shaft, and persists chiefly in the extremities. Destruction of the central part and formation of subperiosteal bone continue until the shaft of the bone has completed its growth.

A typical long bone is developed from three primary centers of ossification, one for the diaphysis or shaft and one for each epiphysis or extremity. Many bones have secondary centers from which processes or apophyses develop.

The foregoing outline accounts for the growth of bones except in regard to length. Increase in length may be explained briefly as follows: Provision for continued ossification at either end of the diaphysis is made by a layer of actively growing cartilage—the

=epiphyseal cartilage=—which intervenes between the diaphysis and the epiphysis. It is evident that so long as this cartilage persists and grows, new bone may continue to be formed at its expense, and increase of length is possible. When the epiphyseal cartilage ceases to grow, it undergoes ossification, the bone is consolidated, and no further increase in length is possible. This fusion takes place at fairly definite periods in the various bones, and it is of value to know the usual times at which it occurs in the larger bones of the limbs at least.

After the bones have reached their full size, the periosteum becomes relatively reduced and inactive so far as its osteogenic layer is concerned; the bone-forming function may be stimulated by various causes, as is well seen in the healing of fractures and the occurrence of bony enlargements.

CHEMICAL COMPOSITION OF BONE

Dried bone consists of =organic= and =inorganic= matter in the ratio of 1 ■ 2 approximately. The animal matter gives toughness and elasticity, the mineral matter hardness, to the bone tissue. Removal of the organic matter by heat does not change the general form of a bone, but reduces the weight by about one-third, and makes it very fragile. Conversely, decalcification, while not affecting the form and size of the bone, renders it soft and pliable. The animal matter when boiled yields gelatin. The following table represents the composition in 100 parts of ox bone of average quality:

Gelatin 33.30 Phosphate of lime 57.35 Carbonate of lime 3.85 Phosphate of magnesia 2.05 Carbonate and chlorid of sodium 3.45 ———————— 100.00

PHYSICAL PROPERTIES OF BONE

Fresh dead bone has a yellowish-white color; when macerated or boiled and bleached, it is white. The specific gravity of fresh compact bone is a little over 1.93. It is very hard and resistant to pressure; a 5-millimeter cube of compact bone of the ox will resist pressure up to 852 pounds, if the pressure be applied in the line of the lamellæ (Rauber). Its tensile strength is estimated to be nearly twice that of oak.

DESCRIPTIVE TERMS

The surfaces of the bones present a great variety of eminences and depressions, as well as perforations. The prominences and cavities may be articular, or non-articular, furnishing attachment to muscles, tendons, ligaments or fascia. A number of descriptive terms are used to designate these features, and the following are some of those in general use:

=Process= (Processus) is a general term for a prominence.

A =tuberosity= (Tuber, Tuberositas) is a large, rounded projection; a =tubercle= (Tuberculum) is a smaller one.

The term =trochanter= is applied to a few prominences, _e. g._, the trochanters of the femur.

A =spine= (Spina) or =spinous process= (Processus spinosus) is a pointed projection.

A =crest= (Crista) is a sharp ridge.

A =line= (Linea) is a very small ridge.

A =head= (Caput) is a rounded articular enlargement at the end of a bone; it may be joined to the shaft by a constricted part, the =neck= (Collum).

A =condyle= (Condylus) is an articular eminence which is somewhat cylindrical; a non-articular projection in connection with a condyle may be termed an =epicondyle=.

A =trochlea= is a pulley-like articular mass.

A =glenoid cavity= (Cavitas glenoidalis) is a shallow articular depression, and a =cotyloid cavity= or =acetabulum= is a deeper one.

The term =facet= is commonly applied to articular surfaces of small extent, especially when they are not strongly concave or convex.

The terms =fossa=, =fovea=, =groove= or =sulcus=, and =impression= are applied to various forms of depressions.

A =foramen= is a perforation for the transmission of vessels, nerves, etc.

A =sinus= or =antrum= is an air-cavity.

Other terms, such as =canal=, =fissure=, =notch=, etc., require no explanation.[3]

VERTEBRAL COLUMN

The =vertebral column= (Columna vertebralis) is the fundamental part of the skeleton. It consists of a chain of median, unpaired, irregular bones which extends from the skull to the end of the tail. In the adult certain vertebræ have become fused to form a single bony mass with which the pelvic girdle articulates. Vertebræ so fused are termed =fixed= or =“false” vertebræ= (Vertebræ immobiles), as distinguished from the =movable= or =“true” vertebræ= (Vertebræ mobiles).

The column is subdivided for description into =five regions=, which are named according to the part of the body in which they are placed. Thus the vertebræ are designated as =cervical=, =thoracic= (or dorsal), =lumbar=, =sacral=, and =coccygeal= or =caudal= (Vertebræ cervicales, thoracales, lumbales, sacrales, coccygeæ). The number of vertebræ in a given species is fairly constant in each region except the last, so that the =vertebral formula= may be expressed (for the horse, for example) as follows:

C_{7}T_{18}L_{6}S_{5}Cy_{15–21}.

[Illustration:

FIG. 4.—FIRST THORACIC VERTEBRÆ OF HORSE.

To illustrate plan of structure of vertebræ.]

The vertebræ in a given region have special characters by which they may be distinguished from those of other regions, and individual vertebræ have characters which are more or less clearly recognizable. All typical vertebræ have a common plan of structure, which must first be understood. The parts of which a vertebra consists are the =body= or =centrum=, the =arch=, and the =processes=.

The =body= (Corpus vertebræ) is the more or less cylindrical mass on which the other parts are constructed. The anterior and posterior extremities of the body are attached to the adjacent vertebræ by intervertebral fibro-cartilages, and are usually convex and concave respectively. The dorsal surface is flattened and enters into the formation of the vertebral canal, while the ventral aspect is rounded laterally, and is in relation to various muscles and viscera. In the thoracic region the body presents two pairs of demifacets (Foveæ costales) at the extremities for articulation with the heads of two pairs of ribs.

The =arch= (Arcus vertebræ) is constructed on the dorsal aspect of the body. It consists originally of two lateral halves, each of which is considered to consist of a pedicle and a lamina. The pedicles form the lateral parts of the arch, and are cut into in front and behind by the =vertebral notches= (Incisura vertebralis cranialis, caudalis). The notches of two adjacent vertebræ form =intervertebral foramina= for the passage of the spinal nerves and vessels; in some vertebræ, however, these are complete foramina instead of notches. The laminæ are plates which complete the arch dorsally, uniting with each other medially at the root of the spinous process.

The body and the arch form a bony ring which incloses the =vertebral foramen= (Foramen vertebrale); the series of vertebral rings, together with the ligaments which unite them, inclose the =vertebral canal= (Canalis vertebralis), which contains the spinal cord and its coverings and vessels.

The =articular processes=, two =anterior= and two =posterior= (Processus articulares craniales, caudales), project from the borders of the arch on either side. They present joint surfaces adapted to those of adjacent vertebræ, and the remaining surface is roughened for muscular and ligamentous attachment.

The =spinous process= (Processus spinosus) is single, and projects dorsally from the middle of the arch. It varies greatly in form, size, and direction in different vertebræ. It furnishes attachment to muscles and ligaments.

The =transverse processes= (Processus transversi) are two in number and project laterally from the side of the arch, or from the junction of the arch and body. In the thoracic region each has a facet for articulation with the tubercle of a rib (Fovea costalis transversalis). They also give attachment to muscles and ligaments.

Some vertebræ have also a =ventral= or =hæmal spine=.

=Mammillary processes= (Processus mammillares) are found in most animals on the last thoracic and anterior lumbar vertebræ between the transverse and anterior articular processes or on the latter.

=Accessory processes= (Processus accessorii), when present, are situated between the transverse and posterior articular processes.

=Development.=—The vertebræ are developed by ossification in the cartilage which surrounds the notochord and forms the sides of the neural canal. There are =three primary centers of ossification=, one for the body and one for each side of the arch. =Secondary centers= appear later for the summit of the spinous process (except in the cervical region), the extremities of the transverse processes, and the thin epiphyseal plates at the extremities of the body.

Sometimes there are at first two centers for the body which soon fuse. The process of ossification extends from the lateral centers to form not only the corresponding part of the arch, but also the processes and a part of the body next to the root of the arch (Radix arcus). In the horse and ox the body and arch are usually fused at birth, but the epiphyses do not fuse till growth is complete. In the pig, sheep, and dog the body and arch are united at birth by cartilage (neurocentral synchondrosis), but fuse in the first few months.

THE RIBS

The ribs (Costæ) are elongated curved bones which form the skeleton of the lateral thoracic walls. They are arranged serially in pairs which usually correspond in number to the thoracic vertebræ. Each articulates dorsally with the spine and is continued ventrally by a =costal cartilage=. Those which articulate with the sternum by means of their cartilages are termed =sternal= or =“true” ribs= (Costæ sternales s. veræ); the remainder are =asternal= or =“false” ribs= (Costæ asternales s. spuriæ). Ribs at the end of the series which have their ventral ends free in the abdominal wall are named =floating ribs= (Costæ fluctuantes). The intervals between the ribs are termed =intercostal spaces= (Spatia intercostalia).

A typical rib[4] consists of a =shaft= and two =extremities=. The =shaft= (Corpus costæ) is band-like and varies much in length, breadth, and curvature. In the case of some ribs the curvature is not uniform, but is most accentuated at a certain point, termed the =angle of the rib= (Angulus costæ); this occurs at a variable distance from the vertebral end, and is usually marked by a rough ridge. The direction also varies; the first rib is almost vertical, while the remainder slope backward in increasing degree. The =external= surface is convex, and the =internal= flattened from edge to edge; on the latter, close to the posterior border, is the =costal groove= (Sulcus costalis), which fades out ventrally. It contains the intercostal vein. The =anterior= and =posterior borders= are thin and sharp on some ribs, rounded on others.

The =vertebral extremity= (Extremitas vertebralis) consists of the =head=, =neck=, and =tubercle=. The =head= (Capitulum costæ) is the actual end of the rib, and is rounded and somewhat enlarged. It presents two facets (Facies articularis capituli costæ) for articulation with the bodies of two adjacent thoracic vertebræ; these surfaces are separated by a groove in which the conjugal ligament is attached. The =neck= (Collum costæ) joins the head to the shaft. It varies in length and diameter. Its outer surface is rough, its inner smooth. The =tubercle= (Tuberculum costæ) projects backward at the junction of the neck and shaft. It has a facet (Facies articularis tuberculi costæ) for articulation with the transverse process of the posterior vertebra of the two with which the head articulates. The tubercle gradually approaches the head in the posterior ribs, and eventually fuses with it.

The =sternal extremity= (Extremitas sternalis) is commonly slightly enlarged, and has a rough depression in which the costal cartilage is embedded.

=Development.=—The ribs are ossified in cartilage from three centers—one each for the shaft (and sternal end), head, and tubercle; the third center does not occur in the last two ribs.

THE COSTAL CARTILAGES

These (Cartilagines costales) are bars of hyaline cartilage which continue the ribs. Those of the sternal ribs articulate with the sternum, while the remainder overlap and are attached to each other to form the =costal arch= (Arcus costalis).

THE STERNUM

The =sternum= or breast-bone is a median segmental bone which completes the skeleton of the thorax ventrally, and articulates with the cartilages of the sternal ribs laterally. It consists of six to eight bony segments (Sternebræ) connected by intervening cartilage in the young subject. Its form varies with that of the thorax in general and with the development of the clavicles in animals in which they are present. Its anterior extremity, the =manubrium sterni= or =presternum=, is specially affected by the latter factor, being broad and strong when the clavicles are well developed and articulate with it (as in man), relatively small and laterally compressed when they are absent (as in the horse) or rudimentary (as in the dog). The cartilages of the first pair of ribs articulate with it. The =body= or =mesosternum= (Corpus sterni) presents laterally, at the junction of the segments, concave facets (Incisuræ costales) for articulation with the cartilages of the sternal ribs. The posterior extremity or =metasternum= presents the =xiphoid= (or ensiform) =cartilage= (Processus xiphoideus); this is thin and plate-like, as in the horse and ox, or narrow and short, as in the pig and dog.

=Development.=—The cartilaginous sternum is formed by the fusion medially of two lateral bars which unite the ventral ends of the first eight or nine costal cartilages, and is primitively unsegmented. The manubrium ossifies from a single center, but the centers for the other segments appear to be primitively paired. The sternum never becomes completely ossified; details in regard to persisting cartilage will be given in the special descriptions. The layer of compact tissue is for the greater part very thin and the spongy substance is open-meshed and very vascular.

THE THORAX

The skeleton of the thorax comprises the thoracic vertebræ dorsally, the ribs and their cartilages laterally, and the sternum ventrally. The =thoracic cavity= (Cavum thoracis) resembles in shape an irregular truncated cone; it is compressed laterally, especially in front, and the dorsal wall or roof is much longer than the ventral wall or floor. The =anterior aperture= (Apertura thoracis cranialis) is bounded by the first thoracic vertebra dorsally, the first pair of ribs and their cartilages laterally, and the manubrium sterni ventrally. The =posterior aperture= (Apertura thoracis caudalis) is bounded by the last thoracic vertebra, the last pair of ribs, the costal arches, and the anterior part of the xiphoid cartilage.

It may be noted here that the diaphragm (which forms the partition between the thoracic and abdominal cavities) does not follow the costal arches in its posterior attachment, so that the posterior ribs enter also into the formation of the abdominal wall.

THE SKULL

The term skull is usually understood to include all of the bones of the head. The head consists of the cranium and the face, and it is therefore convenient to divide the bones into cranial and facial groups.

The =cranial bones= (Ossa cranii) inclose the brain with its membranes and vessels and the essential organs of hearing. They concur with the facial bones in forming the orbital and nasal cavities, in which the peripheral organs of sight and of smell are situated.

The =facial bones= (Ossa faciei) form the skeleton of the oral and nasal cavities, and also support the larynx and the root of the tongue.

Most of the bones of the skull are flat bones, developed in membrane; those of the cranial base may be classed as irregular, and are cartilage bones. Only two form permanent movable joints with other parts of the skull. The mandible or lower jaw-bone forms diarthrodial joints with the temporal bones, and the hyoid bone is attached to the latter by bars of cartilage. The other bones form immovable joints, most of which disappear with age.

In order to study the separate bones, skulls of young subjects are necessary, since later most of the lines of demarcation become effaced. The relations of each bone to its surroundings should be specially noted, since the final object is to understand the skull as a whole. In the descriptions which follow the skull is considered with its long axis horizontal, and that of the horse will serve as a type.

THE BONES OF THE THORACIC LIMB

The thoracic limb consists of four chief segments, viz., the shoulder girdle, the arm, the forearm, and the forefoot or manus.

The =shoulder girdle= (Cingulum extremitatis thoracicæ), when fully developed, consists of three bones—the =scapula= or shoulder-blade, the =coracoid=, and the =clavicle= or collar-bone. In the domesticated mammals only the scapula, a large, flat bone, is well developed, and the small coracoid element has fused with it, while the clavicle is either absent or is a small rudiment embedded in the mastoido-humeralis muscle. There is therefore no articulation of the shoulder with the axial skeleton.

The shoulder girdle is fully developed in birds and the lower mammals (monotremata). In the higher mammals the coracoid is reduced to the coracoid process of the scapula, and the development of the clavicle is in conformity with the function of the limb. Thus in typical quadrupeds, such as the horse and ox, in which the forelimbs are used only for support and locomotion, the clavicle is absent. Other animals which use these limbs for grasping, burrowing, climbing, etc. (_e.g._, man, apes, moles), have well-developed clavicles which connect the scapula with the sternum.

The =arm= (Brachium) contains a single long bone, the humerus or arm bone.

In the =forearm= (Antibrachium) are two long bones, the =radius= and =ulna=. These vary in relative size and mobility. In the horse and ox the two bones are fused, and the lower part of the limb is fixed in the position of pronation. The radius is placed in front and supports the weight. The ulna is well developed only in its upper part, which forms a lever for the extensor muscles of the elbow. In the pig the ulna is the larger and longer of the two bones, but is closely attached to the back of the radius. In the dog the ulna is also well developed and a small amount of movement is possible between the two bones.

The =forefoot= or =hand= (Manus) consists of three subdivisions, viz., the =carpus=, =metacarpus=, and =digit= or =digits=.

The =carpus=, popularly termed the “knee” in animals, and homologous with the wrist of man, contains a group of short bones (Ossa carpi). These are typically eight in number and are arranged in two transverse rows—a proximal or antibrachial, and a distal or metacarpal. The bones of the proximal row, named from the radial to the ulnar side (_i. e._, from within outward), are the =radial=, =intermediate=, =ulnar=, and =accessory= carpal bones. The bones of the distal row are designated numerically, in the same direction, as =first=, =second=, =third=, and =fourth= carpal bones.

This nomenclature, introduced by Gegenbaur, and now used largely by comparative anatomists, seems decidedly preferable to the variety of terms borrowed from human anatomy and based on the form of the bones in man. The following table of synonyms in common use is appended for comparison. The Latin terms and abbreviated notations are given in parenthesis.

Radial (Os carpi radiale, Cr) Scaphoid Intermediate (Os carpi intermedium, Ci) Semilunar Ulnar (Os carpi ulnare, Cu) Cuneiform Accessory (Os carpi accessorium, Ca) Pisiform First carpal (Os carpale primum, C1) Trapezium Second carpal (Os carpale secundum, C2) Trapezoid Third carpal (Os carpale tertium, C3) Os magnum Fourth carpal (Os carpale quartum, C4) Unciform

The central carpal bone (Os carpi centrale) is omitted, since it is not a separate element in the animals under consideration here.

The =metacarpus= contains typically five =metacarpal bones= (Ossa metacarpalia I–V), one for each digit; they are long bones and are designated numerically from within outward. This arrangement occurs in the dog, although the first metacarpal is much smaller than the others, and the second and fifth are somewhat reduced. Further reduction has taken place in the other animals, resulting in the perissodactyl and artiodactyl forms. In the horse the first and fifth metacarpals are absent, the third is the large supporting metacarpal bone and carries the single digit, while the second and fourth are much reduced. In artiodactyls (_e. g._, ox, sheep, pig) the third and fourth are the chief metacarpals and carry the well developed digits; they are fused in the ox and sheep. The others are variously reduced or absent as noted in the special descriptions to follow.

The fossil remains of the ancestors of the existing Equidæ illustrate in a most complete manner the reduction which has occurred in this respect. The earliest known ancestor of the horse, Eohippus or Hyracotherium of the Lower Eocene, had four well developed metacarpal bones, each of which carried a digit; the first metacarpal bone was small. Eleven intermediate stages show the gradual evolution of the race from this primitive animal, which was about the size of the domestic cat. There is reason to believe that earlier forms had five digits.

The =digits= (Digiti manus) are homologous with the fingers of man, and are typically five in number. They are designated numerically from the radial to the ulnar side, in correspondence with the metacarpus. The full number is present in the dog. In the ox and pig the third and fourth are well developed and support the weight, while the second and fifth are reduced. The existing horse has a single digit, the third of his polydactyl ancestors. The skeleton of each fully developed digit consists of three

=phalanges= and certain =sesamoid bones=. The =first= or =proximal phalanx= (Phalanx prima) articulates with the corresponding metacarpal bone above and with the =second= or =middle phalanx= (Phalanx secunda) below. The =third= or =distal phalanx= (Phalanx tertia) is inclosed in the hoof or claw, and is modified to conform to the latter. The =sesamoid bones= (Ossa sesamoidea) are developed along the course of the flexor tendons or in the joint capsules. Two =proximal sesamoids= (Ossa sesamoidea phalangis primæ) occur at the flexor side of the metacarpo-phalangeal joint and form a pulley for the flexor tendon. The =distal sesamoids= (Ossa sesamoidea phalangis tertiæ) are similarly placed between the deep flexor tendon and the joint between the second and third phalanx; they are absent in the dog, which has a small sesamoid on the extensor side of the metacarpo-phalangeal joints, and often at the proximal interphalangeal joint also.

Numerous cases are recorded of the occurrence of supernumerary digits (hyperdactylism) in the horse and other animals. In some pigs, on the other hand, the two chief digits are fused, and the condition appears to be inherited.

THE BONES OF THE PELVIC LIMB

The pelvic limb, like the thoracic, consists of four segments, viz., the pelvic girdle, thigh, leg, and the hind foot or pes; the last is subdivided into tarsus, metatarsus, and digits.

The =pelvic girdle= (Cingulum extremitatis pelvinæ) consists of the =os coxæ= or hip bone, which joins its fellow of the opposite side ventrally at the symphysis pelvis, and articulates very firmly with the sacrum dorsally. The two coxal bones, together with the sacrum and the first two or three coccygeal vertebræ, constitute the bony pelvis. The os coxæ consists originally of three flat bones, the =ilium=, =ischium=, and =pubis=, which meet at the acetabulum, a large cotyloid cavity that articulates with the head of the femur. These three parts are fused before growth is complete, but are considered separately for convenience of description. The =ilium= (Os ilium) is situated in the lateral wall of the pelvis, the =pubis= (Os pubis) in the anterior part, and the =ischium= (Os ischii) in the posterior part of the ventral wall.

The =thigh= (Femur), like the arm, contains a single large, long bone, the =femur= or thigh bone (Os femoris). This articulates with the acetabulum above and the tibia and patella below.

The skeleton of the leg (Crus) comprises three bones (Ossa cruris), viz., the =tibia=, =fibula=, and =patella=. The =tibia= is a large prismatic long bone which supports the weight, and articulates below with the tibial tarsal bone. The =fibula= is situated along the outer border of the tibia, from which it is separated by the =interosseous space= of the leg. It is much more slender than the tibia and does not articulate with the femur. In the pig and dog it has a complete shaft and two extremities, but in the horse and ox it is much reduced and otherwise modified. The =patella= or “knee-cap” is a short bone which articulates with the trochlea of the distal end of the femur; it is to be regarded as a large sesamoid bone intercalated in the tendon of the quadriceps femoris muscle.

The =tarsus= or “hock” consists of a group of short bones (Ossa tarsi) numbering five to seven in the different animals. The proximal or crural row consists of two bones, the =tibial= and =fibular tarsals=; the former is situated at the inner or tibial side, and has a trochlea for articulation with the distal end of the tibia; the latter, situated externally, has a process, the =tuber calcis=, which projects upward and backward and constitutes a lever for the muscles which extend the hock joint. The distal or metatarsal row consists of four bones when seven tarsal elements are present, as in the pig and dog. They are best designated numerically as =first tarsal=, =second tarsal=, etc. The =central tarsal= is interposed between the rows.

The preceding terms are anglicized abbreviations of those introduced by Gegenbaur into comparative anatomy. The Latin names and synonyms are given in the following table.

Tibial (Os tarsi tibiale, Tt.) Astragalus or Talus Fibular (Os tarsi fibulare, Tf.) Calcaneus or Os calcis Central (Os tarsi centrale, Tc.) Scaphoid or Navicular First Tarsal (Os tarsale primum, T1) First or internal cuneiform Second Tarsal (Os tarsale secundum, T2) Second or middle cuneiform Third Tarsal (Os tarsale tertium, T3) Third or external cuneiform Fourth Tarsal (Os tarsale quartum, T4) Cuboid.

The =metatarsal= and =digital bones= resemble in general those of the corresponding regions of the thoracic limb; the differential features will be noted in the special descriptions.

THE SKELETON OF THE HORSE

The skeleton of the horse consists of 205 bones, as shown in the following table.

Vertebral column 54 Ribs 36 Sternum 1 Skull (including auditory ossicles) 34 Thoracic limbs 40 Pelvic limbs 40 ———— 205

In this enumeration the average number of coccygeal vertebræ is taken to be 18, the temporal and os coxæ are not divided into parts, the usual number of carpal and tarsal elements is taken, and the sesamoids are included.

THE VERTEBRAL COLUMN

The vertebral formula of the horse is $C_{7}T_{18}L_{6}S_{5}Cy_{15–21}$.

[Illustration:

FIG. 6.—CERVICAL VERTEBRÆ OF HORSE, DORSAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 7.—CERVICAL VERTEBRÆ OF HORSE, VENTRAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE CERVICAL VERTEBRÆ

These are quadrangular, massive, and longer than the vertebræ of other regions; they decrease in length from the second to the last. The =third=, =fourth=, and =fifth= are typical, and have the following characters:

1. The =bodies= are long as compared with those of other vertebræ. Each presents a median =ventral spine= or =crest=, which becomes more prominent as it is traced backward, and is tuberculate at its posterior end. The =lateral aspect= is concave. The =dorsal surface= has a flat central area which is narrow in the middle of the vertebræ, and wide at either end; it gives attachment to the superior common ligament. On either side of this area is a groove which lodges the longitudinal spinal vein. These lateral grooves are connected at the middle of the surface by a transverse furrow, in which there are several foramina through which veins emerge from the spongy substance of the body. The =anterior extremity= presents a head which has an oval articular surface, strongly convex, and wider above than below. The =posterior extremity= is larger and has a nearly circular cotyloid cavity.

[Illustration:

FIG. 8.—LAST CERVICAL AND FIRST THORACIC VERTEBRÆ OF HORSE, LATERAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

2. The =arches= are large and strong. They are perforated on either side by a foramen which communicates with the foramen transversarium. The vertebral notches are large.

3. The =articular processes= are large. Their articular surfaces are extensive, oval in outline, and slightly concave; the anterior ones are directed upward and inward, the posterior downward and outward. The remaining surface is mainly roughened for ligamentous and muscular attachment. A crest connects the articular processes of the same side on the fourth and fifth; on the third it does not reach the anterior process.

4. The =transverse processes= are large and plate-like. Each arises by two roots, one from the arch and one from the body; between these is the =foramen transversarium=, through which the vertebral artery passes. The process divides externally into

anterior and posterior branches, which are thickened and rough for muscular attachment.

5. The =spinous process= is represented by a crest (Crista spinosa), which widens behind, and is connected by ridges with the posterior articular processes.

The =sixth= cervical vertebra has the following distinctive features: It is shorter and wider than the fifth. The =arch= is large, especially posteriorly. The =posterior articular= processes are shorter, thicker and further apart; they are connected with the anterior ones by a thick ridge. The =spinous process= is less rudimentary; it is half an inch or more (ca. 1.5 cm.) in height. The =transverse processes= have three branches; the third part is a thick, almost sagittal plate, which forms with its fellow and the body a wide ventral groove on the posterior part of the vertebra; the other branches correspond to those of the typical vertebræ, but are short and thicker. The =foramen transversarium= is large; below its posterior end is a fossa. The =ventral crest= is small and is less prominent posteriorly.

The third branch of the transverse process and the fossa are sometimes absent on one side.

The =seventh= cervical vertebra is readily distinguished by the following characters: It is =shorter= and =wider= than the others. The =body= is flattened dorso-ventrally and wide, especially behind; here it has a =demifacet= on either side for articulation with part of the head of the first rib. The =arch= and its =notches= are large. The =anterior articular processes= are wider and longer than the posterior pair. The =spinous process= is an inch or more (ca. 3 cm.) in height. The =transverse process= is undivided, and has no foramen transversarium. The ventral crest is replaced by a pair of tubercles.

In some specimens a large foramen transversarium is present on one side or (rarely) on both.

FIG. 9.—ATLAS OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 10.—ATLAS OF HORSE, POSTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE ATLAS

This vertebra is decidedly atypical in form and structure. The body and spinous process are absent. It has the form of a strong ring, from which two curved plates, the =wings=, project laterally. The ring incloses a very large vertebral foramen, and consists of two =lateral masses= connected by =dorsal= and =ventral arches=.

The =lateral masses= (Massæ laterales) present two deep oval =anterior articular cavities= (Foveæ articulares craniales) which receive the occipital condyles; they are separated by a wide notch above and a narrow one below. The outer margin is also notched, and a triangular non-articular depression cuts into the inner part of each cavity. The =posterior articular surfaces= (Facies articulares caudales) are somewhat saddle-shaped; they are confluent on the ventral arch below, but are widely separated above, and do not conform in shape to the corresponding surfaces of the axis.

The =dorsal arch= (Arcus dorsalis) presents a median =dorsal tubercle= (Tuberculum dorsale) and is concave below. It is perforated on either side near its anterior margin by the =intervertebral foramen=. The =anterior border= is deeply notched, and the =posterior= is thin and concave.

The =ventral arch= (Arcus ventralis) is thicker, narrower, and less curved than the dorsal. On its lower surface is the =ventral tubercle= (Tuberculum ventrale), into which the terminal tendon of the longus colli muscle is inserted. The upper face has posteriorly a transversely concave articular surface (Fovea dentis), on which the dens or odontoid process of the axis rests. In front of this is a transverse rough excavation for the attachment of the odontoid ligament.

The =wings= (Alæ) are modified transverse processes. They are extensive curved plates which project outward, downward, and backward from the lateral masses. The dorsal surface is concave. Between the ventral aspect of the wing and the lateral mass is a cavity, the =fossa atlantis=; in this there is a foramen which opens into the vertebral canal. The =border= is thick and rough. Two foramina perforate each wing. The anterior one, the =foramen alare=, is connected with the intervertebral foramen by a short groove. The posterior one is the =foramen transversarium=.

=Development.=—The atlas ossifies from =three= or =four centers=, one or two for the ventral arch, and one on either side for each lateral mass, wing, and half of the dorsal arch. At birth the bone consists of three pieces—the ventral arch and two lateral parts, which are separated by a layer of cartilage in the dorsal median line. These parts are usually fused at about six months.

[Illustration:

FIG. 11.—FIRST THREE CERVICAL VERTEBRÆ OF HORSE, LATERAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE AXIS

The =axis= (Epistropheus) is the longest of the vertebræ, and is characterized by the presence of the odontoid process, which projects from the anterior part of the body.

The =body= has a median ventral crest which terminates in a tubercle behind. The anterior extremity presents centrally the =odontoid process= (Dens); this has a convex articular surface ventrally for articulation with the ventral arch of the atlas, and two rough depressions for the attachment of the odontoid ligament dorsally. Flanking this on either side are the modified =anterior articular processes=, which have saddle-shaped articular surfaces confluent below with that of the dens. The posterior extremity has the usual cavity.

The =arch= presents in the young subject a notch on each side of its anterior border; this is converted into a foramen by a ligament which usually ossifies later. The posterior border has the usual notches.

The =posterior articular processes= are typical.

The =transverse processes= are small, single, and project backward. The =foramen transversarium= is small.

The =spinous process= is very large and strong. Its free border is rough, thickens posteriorly, and is continued to the articular processes by two ridges. The lateral surfaces are concave and rough for muscular attachment.

=Development.=—The axis has =six= or =seven centers= of ossification. In addition to the usual five, one or two appear for the dens, which is regarded as the displaced body of the atlas. A nucleus behind the dens, which remains distinct to three or four years of age, is considered by Lesbre to be the head of the axis.

[Illustration:

FIG. 12.—OCCIPITAL BONE AND FIRST THREE CERVICAL VERTEBRÆ OF HORSE, DORSAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE THORACIC VERTEBRÆ

These (Vertebræ thoracales) are usually eighteen in number in the horse, but there are sometimes nineteen, rarely seventeen. As regional characters we note the surfaces for articulation with the ribs and the length and form of the spinous processes. Those in the middle of the series are the most typical and present the following features:

1. The =bodies= are short and constricted in the middle. The ends are expanded and have articular surfaces which are not strongly curved. On the upper part of each side are anterior and posterior =costal facets= (Fovea costalis cranialis, caudalis), which, with those of adjacent vertebræ, form sockets for the heads of the ribs.

2. The =arches= are small. Their posterior notches are relatively large and are often converted into foramina.

[Illustration:

FIG. 13.—THIRD, FOURTH, AND FIFTH THORACIC VERTEBRÆ OF HORSE, LATERAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

3. The =articular processes= are small. The anterior pair are in fact represented only by two oval facets on the anterior part of the laminæ which face almost directly upward. The posterior pair spring from the base of the spinous process; their facets face almost directly downward.

4. The =transverse processes= are short, thick, and tuberous at the free end. Each has a =facet= (Fovea transversaria) for articulation with the tuberosity of the rib which has the same serial number.

5. The =spinous process= is large, narrow, and slopes upward and backward. The anterior border is thin, the posterior wider and furrowed. The summit is expanded and rough.

The =first thoracic vertebra= is easily recognized by the following specific characters: The body is wide and flattened dorso-ventrally. In front it has a head like the cervical vertebræ, and behind a cavity somewhat deeper than any other thoracic vertebra. Two =costal facets= are found on either side, and a well-marked spine ventrally. The =arch= is large and strong, and has large notches. The =articular processes= are much larger than those of other thoracic vertebræ, and resemble a good deal those of the seventh cervical in form. The =transverse processes= are short and thick, and each has on its ventral aspect a large concave facet for articulation with the tubercle of the first rib. The spinous process is curved backward and tapers to a point. Its length is usually about three or four inches (ca. 8 to 10 cm.). It may be mistaken at first glance for the last cervical, but is promptly identified by the three costal facets on each side and the length of the spine.

The =last thoracic vertebra= is distinguished by the absence of the posterior pair of costal facets, and the confluence of the anterior pair with those on the transverse processes.

[Illustration:

FIG. 14.—THIRD THORACIC VERTEBRÆ AND UPPER PART OF RIB OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 15.—LOWER PART OF NINTH THORACIC VERTEBRA OF HORSE, POSTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The serial position of others may be determined at least approximately by the following data: (1) The bodies gradually diminish in length and width to the middle of the region and then increase slightly. Their costal facets become smaller and less concave from first to last. The ventral crest is distinct on three or four vertebræ at either end of the region. (2) The transverse processes diminish in size and are placed lower down as they are traced backward. Their costal facets become smaller and lower in position; on the last (and sometimes on its predecessor also) it fuses with the costal facet of the body. The upper non-articular part of the process gradually becomes more sharply defined, and in the last four or five separates to form the =mammillary process=. (3) The spinous processes increase in length to the third and fourth, and then gradually diminish to the fifteenth, beyond which they have about the same length. The backward inclination is most pronounced in the second, the sixteenth is vertical, and the last two are directed a little forward. The longest spines (_i. e._, those of the withers) are the thickest and have expanded summits which remain more or less cartilaginous; the others are more plate-like, and are surmounted by a thick lip. The second spine is more than twice as large as the first. The summits of the fourth and fifth usually form the highest point of the withers.

=Development.=—There are =six= or =seven centers=, three for the body, two for the arch, and one for the spinous process; some of the latter have an additional center for the summit.

THE LUMBAR VERTEBRÆ

The =lumbar vertebræ= (Vertebræ lumbales) are usually six in number in the horse. They are characterized by the size and form of their transverse processes.

The =bodies= of the first three are triangular on cross-section, and present a distinct ventral crest. From the fourth backward they become wider and flatter and the ventral crest fades out.

[Illustration:

FIG. 16.—FIRST THORACIC VERTEBRA AND UPPER PART OF FIRST RIB OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =arches= of the first two or three are about equal in size and similar to that of the last thoracic; from the fourth they decrease noticeably in breadth and height.

[Illustration:

FIG. 17.—LAST TWO THORACIC AND FIRST LUMBAR VERTEBRÆ OF HORSE, LATERAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =anterior articular processes= are fused with the mammillary processes, and present superiorly concave surfaces for articulation with the posterior pair of the preceding vertebra. The =posterior articular processes= project distinctly from the arch at the base of the spinous process, and have ventrally convex articular surfaces, which fit into the grooved surfaces of the anterior pair of the next vertebra.

The =transverse processes= are large plates, flattened dorso-ventrally, which project outward and usually curve slightly downward; their length increases to the third and fourth, and then diminishes to the last, which is the shortest. The first one or two usually curve somewhat backward, the last two decidedly forward. Those of the fifth have an oval concave facet on the inner part of the posterior border for articulation with the sixth process; the latter has a corresponding convex facet on the anterior border, and a larger concave surface on the posterior border for articulation with the wing of the sacrum. Sometimes the fifth process has a small surface for articulation with the fourth. The inner part of the sixth process is thick, the outer part thinner, narrower, and curved forward. The inner part of the fifth is also somewhat thickened.

The =spinous processes= resemble those of the last two thoracic vertebræ. They are usually about equal in height, but minor differences are common, and the width diminishes in the last three.

=Development.=—This is similar to that of the thoracic vertebræ. The extremities of the transverse processes remain cartilaginous for some time after ossification is otherwise complete.

[Illustration:

FIG. 18.—SECOND LUMBAR VERTEBRA OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The transverse processes of this region are considered equivalent to the proper transverse process + the costal element, and hence the distinctive term processus lateralis (s. costarius) has been proposed. The occurrence of a lumbar rib in connection with the transverse process of the first lumbar is not rare. Reduction of the number to five has been observed frequently, and may or may not be compensated by an additional thoracic vertebra. This variation is not more common in certain races as Sanson and others have maintained. Very few cases are recorded of seven lumbar vertebræ—especially with the normal thoracic number. An anomalous vertebra with mixed thoracic and lumbar characters sometimes occurs at the junction of the two regions.

THE SACRUM

The =sacrum= (Os sacrum) is formed by the fusion of five vertebræ usually, and is conveniently described as a single bone. It is triangular in form and is wedged in between the ilia, with which it articulates very firmly on each side. Its long axis is gently curved, and slightly oblique, so that the posterior end is a little higher than the anterior. It presents two surfaces, two borders, a base, and an apex.

The =dorsal surface= presents centrally the five sacral spines, which are directed upward and backward, and have (with the exception of the first) tuberous summits which are sometimes bifid.

The first spine is relatively thin and narrow, and is not so high as the internal angle of the ilium. The second is the longest, and the height diminishes rapidly to the last. The bases of the spines are often fused in old subjects.

On either side of the spines is a groove, in which are the four =dorsal sacral foramina= (Foramina sacralia dorsalia); the dorsal branches of the sacral nerves emerge through them.

The =ventral= or =pelvic surface= (Facies pelvina) is concave in its length, wide in front, narrow behind. It is marked by four more or less distinct =transverse lines= (Linæ transversæ), which indicate the demarcation of the bodies of the vertebræ. At the ends of these lines are the =ventral sacral foramina= (Foramina sacralia ventralia), which are larger than the dorsal series and diminish in size from first to last; they transmit the ventral divisions of the sacral nerves.

The dorsal and ventral foramina communicate with the sacral canal and are together equivalent to the usual intervertebral foramina.

[Illustration:

FIG. 19.—SACRUM OF HORSE, DORSO-LATERAL VIEW.

_C_, Body of first sacral vertebra; _A_, arch of first vertebra; _Cs_, sacral canal; _P.s._ 1–5, sacral spines; _P.t._, wings of sacrum; 1, 1′, surfaces for articulation with transverse processes of last lumbar vertebra; _F.a._, auricular surface; 2, 2′, articular processes; 3–6, dorsal sacral foramina; 7, interarcuate space; 8, lateral border; _h_, apex. (Struska, Anat. d. Haustiere.)]

The =lateral borders= are rough, thick in front, thin behind.

The =base= (Basis ossis sacri) is directed forward, and is relatively very wide. It presents centrally the =body= of the first sacral segment, which is wide transversely, flattened dorso-ventrally, and has a rounded surface which articulates with the last lumbar vertebra through the medium of an intervertebral fibro-cartilage. The ventral margin projects slightly, forming the =promontory= (Promontorium). Above the body is the entrance to the sacral canal, flanked by a pair of =articular processes=, which project upward and forward from the arch, and have concave surfaces internally for articulation with those of the last lumbar vertebra. On each side of these is a smooth notch which is converted into a foramen by apposition with the last lumbar. The lateral parts of the base, the =wings= or =alæ= (Alæ sacrales), are strong prismatic masses with pointed ends, which result from the fusion of the first with part of the second transverse process. Each has in front a large, oval, slightly convex surface for articulation with the transverse process of the last lumbar. Posteriorly there is an elongated oval area which faces upward, backward, and outward. This is the =auricular surface= (Facies auricularis), which articulates with the ilium; it is slightly concave in its length, and somewhat rough and irregular. The rest of the dorsal surface of the wing is roughened for ligamentous attachment, while the ventral surface is smooth.

The =apex= (Apex ossis sacri) is the posterior aspect of the last sacral vertebra and is quite small. It presents the elliptical flattened surface of the body, above which is the triangular posterior opening of the sacral canal, surmounted by the last sacral spine. There is a pair of narrow notches between the arch and body, above which rudiments of articular processes may occur.

The name =sacral canal= (Canalis sacralis) is applied to that part of the vertebral canal which traverses the sacrum. Its anterior part is large and has the form of a triangle with the angles rounded off; its width is about twice its height. Traced backward it is seen to diminish in size rapidly, and the posterior opening is quite small and triangular.

The term =lateral part= (Pars lateralis) designates the portion external to the foramina, which results from the fusion of the transverse processes.

[Illustration:

FIG. 20.—FIRST COCCYGEAL VERTEBRA OF HORSE, LEFT VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 21.—FIRST COCCYGEAL VERTEBRA OF HORSE, DORSAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

=Development.=—The several sacral vertebræ ossify in the typical manner. Separate centers for costal elements in the lateral parts have not yet been found in the domesticated animals. Fusion begins in front, and is usually not complete behind till near adult age. The lateral parts unite before the bodies. It is rather curious that the epiphyseal plates of adjacent segments unite with each other before they fuse with the main portion of the bodies.

THE COCCYGEAL VERTEBRÆ

These (Vertebræ coccygeæ) vary considerably in number, but eighteen may be taken as an average. From first to last they become reduced in size and, with the exception of a few at the beginning of the series, consist of bodies only. The first three have bodies which are somewhat flattened dorso-ventrally, constricted in the middle, and have at the ends slightly convex, elliptical, articular surfaces. The ventral surface has a median groove for the coccygeal artery. The arch is small and triangular; it is formed of two flat plates which are prolonged to form a short spinous process with a thickened and often double summit. The anterior notches are absent. Functional articular processes are not present, but small rudiments of the anterior pair commonly occur. The transverse

processes are relatively large plates which project horizontally outward. Further back the arch becomes incomplete, open above, and soon disappears; the transverse processes gradually fade out, and the vertebræ are reduced to cylindrical rods of diminishing size. The last one has a pointed end.

=Variations.=—The number is said by good observers to vary between fourteen and twenty-one. In old age the first is often fused with the sacrum, and sometimes with the second. The arch of the third may be open.

THE VERTEBRAL COLUMN AS A WHOLE

In the mid-dorsal line is the series of =spinous processes=, which are low ridges in the cervical region with the exception of the second and seventh, reach their maximum height at the fourth and fifth thoracic vertebræ, and diminish to the fifteenth or sixteenth thoracic. Behind this they are about equal in height as far as the last lumbar and first sacral, which are somewhat lower. The second sacral spine is about as high as the middle lumbar; behind this they diminish rather rapidly in height and fade out about the third coccygeal. Their =inclination= backward is most decided at the second thoracic, diminishes from the sixth or seventh to the fifteenth or sixteenth, which is vertical and is termed the =anticlinal= or =diaphragmatic vertebra.= Behind this they are inclined a little forward until the sacrum is reached; here there is an abrupt change to the backward inclination, so that a considerable interspinous angle is formed.

On either side of the spinous processes is a =vertebral groove= which contains the deep muscles of the spine. The floor of the groove is formed by the laminæ and articular processes. It is wide in the neck and narrows progressively in the back.

Viewed from the side, the column presents a series of curves. When the head and neck are in the ordinary neutral position, the anterior part of the cervical spine forms a gentle curve, concave ventrally. The posterior cervical and first thoracic vertebræ form a more pronounced curve in the opposite direction. At the junction of the cervical and thoracic regions there is a marked change of direction, forming a ventral projection or angle. At the second thoracic vertebra a gentle curve, concave ventrally, begins. This is continued to the lumbo-sacral junction, where there is a change of direction, and hence a promontory. The sacrum has a variable, but never very pronounced, ventral concave curvature, which is continued in a much accentuated form in the coccygeal region. It may be remarked that a line through the summits of the spines does not correspond to these curves formed by the bodies.

The =vertebral canal=, of course, corresponds in curvature to the bodies. Its =caliber= varies greatly at different points. The greatest diameter (ca. 5 cm.) is in the atlas, where it contains the dens of the axis in addition to the spinal cord, and provision must be made for extensive movement. It is very much smaller in the axis (ca. 2.5 cm. wide, 3 cm. high). It widens considerably at the junction of the cervical and thoracic regions to accommodate the cervical enlargement of the spinal cord. Beyond this it diminishes, and is smaller in the middle of the back than at any preceding point; this is correlated with the small size of the spinal cord and the very limited movement of the spine. At the middle of the lumbar region it again widens considerably to contain the lumbar enlargement of the spinal cord. The caliber diminishes very rapidly from the second sacral segment backward, and the canal ceases to be complete at the fourth coccygeal vertebra.

The =articular processes= are very large and wide apart in the neck, greatly reduced and much closer together in the back, larger and interlocking in the lumbar region.

The =transverse processes= are large and outstanding in the neck, where they form the outer boundary of a ventral groove occupied by the longus colli muscle. In the back they are short and stout, and are characterized by the facets for the tubercles of the ribs. On the first thoracic vertebra this facet is large, deeply concave, and situated almost directly outward from the cavity for the head of the rib; traced backward it becomes smaller and flatter, and gradually comes to lie behind the cavity for the head of the rib, with which it is fused on the last and often also on the next to the last thoracic vertebra. The processes in the lumbar region have a characteristic elongated plate-like form. In the sacral region they are fused to form the wings and lateral parts of the sacrum. In the coccygeal region they are at first of considerable size relatively, but undergo rapid reduction, and disappear at the fifth or sixth vertebra.

The cavities for the heads of the ribs diminish progressively in size and depth from first to last.

The =mammillary processes= are usually distinct on the fourteenth to the seventeenth thoracic vertebræ. In front of these they blend with the transverse, behind with the anterior articular processes.

The length of the vertebral column (including the intervertebral fibro-cartilages) in a horse of medium size is about 260 to 265 cm. (ca. 8 feet 8 inches to 8 feet 10 inches). The relative lengths of the various regions appear to vary most in the neck and back.

The table below gives the measurements in centimeters in a trotting stallion of medium size and in an adult Percheron stallion. The percentages are in round numbers.

■■■

inclines a little forward, the second is about vertical, while behind this they slope backward in increasing degree, so that a plane tangent to the ventral ends of the last pair cuts the third lumbar vertebra. The =head= and =tubercle= diminish in size from first to last. Their relative positions change in that the tubercle of the first rib lies almost directly outward from the head, while further back it gradually comes to lie behind it. The =neck= is longest on the longest ribs, and is absent on the last two or three. A costo-transverse foramen is formed between the neck and the transverse process.

=Development.=—The ribs ossify in cartilage from =three centers=, one each for the shaft, head, and tubercle; the third center is absent in some of the posterior ribs.

=Variations.=—A nineteenth rib on one side or both is not rare. It is usually imperfectly developed and quite variable. In some cases it is a mere strip of cartilage connected by ligament with the first lumbar transverse process; in other cases it is ossified, and may be fused with the process; in others again it is connected with an additional presacral vertebra which may be thoracic or lumbar or ambiguous in character. It is commonly floating, but may be attached to the eighteenth. Reduction in number is uncommon. Fusion of adjacent ribs sometimes occurs.

THE COSTAL CARTILAGES

[Illustration:

FIG. 23.—STERNUM AND COSTAL CARTILAGES OF HORSE, VENTRAL VIEW. (After Ellenberger-Baum, Anat. f. Künstler.)]

The first costal cartilage is an inch or more (2.5 to 3 cm.) in length. The upper part is very wide and thick. The sternal end is small. The two articulate with each other as well as with the sternum. The cartilages of the other sternal ribs increase progressively in length and become more rounded. The sternal end is expanded and has an elliptical convex facet for articulation with the sternum. The cartilages of the asternal ribs are long, slender, and pointed. The ninth is the longest, and is very firmly attached to the eighth; behind this they diminish progressively in size, and are attached to each other by elastic tissue. Except in the case of the first, the cartilage does not continue the direction of the rib, but forms with the latter an angle which is open in front, and decreases in obtuseness from second to last.

More or less extensive ossification is to be regarded as a normal occurrence, especially in the cartilages of the sternal ribs.

THE STERNUM

The sternum of the horse is shaped somewhat like a canoe; it is compressed laterally, except in its posterior part, which is flattened dorso-ventrally. It is inclined obliquely so that the posterior end is about six to eight inches (15 to 20 cm.) lower than the anterior.

The =dorsal surface= has the form of a very narrow isosceles triangle with the apex in front. It is concave longitudinally, flattened transversely.

The =lateral surfaces= are convex above, slightly concave below, and diminish in extent behind. Each presents on its upper part seven =articular cavities= (Foveæ costales), which receive the sternal ends of the second to the eighth costal cartilages inclusive. These cavities are situated in series at the intersternebral junctions. The first four are elliptical in outline with the long diameter vertical, and are separated by considerable regular intervals. The others are progressively smaller, more circular, and closer together. The area below these cavities gives attachment to the pectoral muscles.

[Illustration:

FIG. 24.—STERNUM OF HORSE, LATERAL VIEW.

The sternebræ are designated by Roman numerals and the costal facets by ordinary figures.]

The =dorso-lateral= borders separate the dorsal and lateral surfaces. They give attachment to the lateral branches of the sternal ligament.

The =ventral border= forms the prominent keel-like crest of the sternum (Crista sterni) which may be felt in the living animal; it fades out behind.

[Illustration:

FIG. 25.—ANTERIOR APERTURE OF THORAX OF HORSE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =anterior extremity= or =manubrium sterni=[5] can be distinctly felt in the central furrow of the breast. It consists of a laterally compressed cartilaginous prolongation, commonly called the =cariniform cartilage=. Its lateral surfaces are flat and furnish attachment to muscles of the breast and neck. The ventral border is rounded, and is continued backward on the body of the bone. The dorsal border is concave and has an articular cavity for the first pair of costal cartilages.

The =posterior extremity= is formed by the =xiphoid= or =ensiform cartilage= (Processus xiphoideus). This is a thin plate, connected in front with the last bony segment by a relatively thick, narrow neck, and expanding in nearly circular form behind and laterally. Its dorsal surface is concave, and gives attachment to the diaphragm. The ventral surface is convex. The free margin is very thin.

=Development.=—At birth the sternum of the horse consists of seven bony segments or sternebræ united by intersternebral cartilages. The last two sternebræ fuse in the second month, but the others do not usually unite completely even in old age. The sternebræ consist of very vascular spongy bone covered by a very thin layer of compact substance. The adult sternum thus consists to a very considerable extent of persisting cartilage, viz., the intersternebral cartilages, the ventral keel, and the extremities; in old age these undergo partial ossification.

THE THORAX

The bony thorax of the horse is remarkably compressed laterally in its anterior part, but widens greatly behind. The =anterior aperture= is oval and very narrow below; in a horse of medium size its greatest width is about 4 inches (10 cm.), and its height 7 to 8 inches (ca. 18 to 20 cm.). The =ventral wall= or =floor= is about 10 inches (40 cm.) long, and the =dorsal wall= or =roof= about 38 to 40 inches (95 to 100 cm.) long. The height from the last segment of the sternum to the seventh or eighth thoracic vertebra is about twice that of the anterior aperture; this is due to the obliquity and divergence of the roof and floor. The greatest width of the posterior aperture is about 20 to 24 inches (50 to 60 cm.). The intercostal spaces increase in width from the first to the seventh or eighth, and then diminish. Their average width is about 1¼ to 1½ inches (3 to 3.5 cm.).

THE BONES OF THE SKULL

(A) BONES OF THE CRANIUM

The bones of the cranium (Ossa cranii) are the Occipital, Sphenoid, Ethmoid, Interparietal, Parietal, Frontal, and Temporal. The first four are single, the others paired.

(After Ellenberger-Baum, Anat. für Künstler.)]

THE OCCIPITAL BONE

The =occipital bone= (Os occipitale) is situated at the posterior part of the cranium, of which it forms the posterior wall and part of the ventral wall or base.[6]

Its lower part is perforated centrally by a large, almost circular opening, the =foramen magnum= (Foramen occipitale magnum), at which the brain and spinal cord join. The foramen is bounded laterally and dorsally by the =lateral parts= of the bone, and ventrally by the =basilar part= or =process=. Above the lateral parts—but not entering into the formation of the foramen magnum—is the =squamous part=.

The =lateral parts= (Partes laterales) bear the =occipital condyles= (Condyli occipitales), which articulate with the atlas. The condyles are obliquely placed, wide apart dorsally, and separated by a small interval ventrally. The articular surface is curved so sharply in the dorso-ventral direction as to form a blunt ridge externally. The cranial surface is concave and smooth. External to the condyle is the =paramastoid= or =styloid process= (Processus jugularis), a strong flattened bar of bone which projects downward and backward; its external surface is convex and roughened for muscular attachment. Between the root of this process and the condyle is a smooth depression, the =condyloid fossa= (Fossa condyloidea inferior); in this is the =hypoglossal foramen= (Foramen hypoglossi), which transmits the nerve of like name.

The =basilar part= or =process= (Pars basilaris) is a strong, somewhat prismatic bar which extends forward from the ventral margin of the foramen magnum. It is much narrower in front than behind. The ventral surface is rounded. The cranial surface is concave and smooth; its posterior part, supports the medulla, and its anterior part has a shallow cavity on which the pons rests. The lateral borders are thin and sharp, and form the inner margin of the =foramen lacerum= (Foramen lacerum et jugulare). The anterior end has, in the young subject, a semicircular, flat, pitted surface which is attached to the body of the sphenoid bone by a layer of cartilage; in the adult there is complete fusion. On the ventral aspect of the junction are tubercles for the attachment of the ventral straight muscles of the head.

[Illustration:

FIG. 28.—VENTRAL SURFACE OF SKULL OF HORSE, POSTERIOR HALF WITHOUT MANDIBLE.

The skull is inclined slightly. (Notation on key Fig. 27.)]

The =squamous part= (Squama occipitalis) is the somewhat quadrilateral mass situated above the lateral portions, from which it remains distinct till the second year. The =outer surface= is crossed by a very prominent ridge, the =occipital crest=; the middle part of this is thick, transverse in direction, and forms the highest point of the skull when the head is in the ordinary position; laterally it becomes thinner and runs downward and forward to join the temporal crest.[7] The crest divides the surface into two very unequal parts; the small anterior area (Planum parietale) presents a median ridge which is the posterior part of the external sagittal crest; the large area below the crest (Planum nuchale) also has a central eminence, the =external occipital protuberance=, on the sides of which the funicular part of the ligamentum nuchæ is attached. The =internal surface= is concave and presents a deep central depression and two shallower lateral ones which adapt it to the surface of the cerebellum.

The occipital bone is connected by suture with the interparietal, two parietals, and two temporals, and by synchondrosis with the sphenoid; the condyles articulate with the atlas.

=Development.=—The occipital ossifies in cartilage from =four centers=, and consists at birth of four pieces as described above.[8] The lateral parts unite with the basilar at three to four months, and with the squama in the second year, when the bone is consolidated.

The parieto-occipital suture and the spheno-occipital synchondrosis are obliterated about the fifth year usually. The temporo-occipital suture partially ossifies in old subjects.

THE SPHENOID BONE

The =sphenoid bone= (Os sphenoidale) is situated in the base of the cranium, its central part lying in front of the basilar part of the occipital. It consists of a central part, the body, two pairs of wings, and two pterygoid processes.

The =body= (Corpus) is a cylindrical bar, flattened dorso-ventrally, and wider in front than behind. Its =ventral surface= (Facies externa) is convex in the transverse direction; and its anterior part is concealed to a large extent by the vomer and pterygoid bones. The =cerebral surface= (Facies cerebralis) presents the following features: (1) In front is a raised, flattened part which is subdivided by a median elevation into two slightly concave lateral areas; this part has a posterior, thin, free margin (Limbus sphenoidalis), which overlies the entrance to the optic foramina. (2) Just behind this and at a lower level is a smooth transverse depression, the

=optic groove= (Sulcus chiasmatis), on which the optic chiasma rests. (3) From each end of this groove the =optic foramen= passes forward and outward to terminate in the posterior part of the orbital fossa.[9] (4) Near the posterior end is a central depression, the =hypophyseal= or =pituitary fossa= (Fossa hypophysea), which lodges the hypophysis cerebri or pituitary body. On each side of this is an ill-defined groove for the internal carotid artery and the cavernous sinus. The =anterior end= is expanded, and is excavated to form the =sphenoidal sinuses.= These cavities extend back as far as the optic groove, and are usually continuous in front with the cavities in the vertical parts of the palate bones; they are separated by a complete septum which is not always median.[10] The =posterior end= is flat and is joined to the basilar part of the occipital; at the line of junction there is dorsally a transverse elevation, the =spheno-occipital= crest (Crista sphenooccipitalis).

The =orbital wings= (Alæ orbitales) curve upward and somewhat outward from the sides of the body of the presphenoid. Their =inner= or =cerebral surfaces= are concave, and are marked by =digital impressions= (Impressiones digitatæ) for the gyri of the cerebrum. The =external surface= is convex and is largely concealed by the overlapping temporal wing and the squamous temporal and frontal bones; a narrow part of it (Facies orbitalis) is uncovered on the inner wail of the orbital cavity at the sphenoidal notch of the frontal bone. The =dorsal border= unites with the frontal bone at the spheno-frontal suture. The =anterior border= joins the ethmoid at the spheno-ethmoidal suture; at its lower part it concurs with the frontal in the formation of the =ethmoidal= (or internal orbital) =foramen=. The =posterior border= is overlapped by the temporal wing and the squamous temporal. The =root= of the wing is perforated by the =optic foramen=. Immediately below and behind the latter (_i. e._, beneath the root) is the =foramen lacerum orbitale= or =orbital fissure=. Below this, and separated from it usually by a thin plate, is a larger opening, the =foramen rotundum=, which is bounded externally by the root of the pterygoid process. Behind these foramina is the =pterygoid crest= (Crista pterygoidea), which is continued downward and forward on the pterygoid process; on its upper part may be found the small and inconstant =trochlear= (or pathetic) =foramen=. Just behind the crest is the =temporal foramen= (For. alare parvum), through which the anterior deep temporal artery emerges from the alar canal of the pterygoid process.

The =temporal wings= (Alæ temporales) extend outward and somewhat upward from the body of the postsphenoid; they are irregularly quadrilateral in outline. The =external surface= (Facies temporalis) enters into the formation of the infratemporal fossa, and bears the pterygoid process on its anterior part; at the junction with the body there is a small groove for the pterygoid nerve. The =internal surface= (Facies cerebralis) presents, at the junction with the body, two longitudinal =grooves= (Sulci nervorum). The outer groove is the larger, and leads forward to the foramen rotundum; it contains the maxillary nerve. The inner groove conducts to the orbital fissure, and contains the third, sixth, and ophthalmic nerves. The outer groove is bounded externally by a thin overhanging crest, on which is a small groove for the fourth nerve. The remainder of the surface is concave and supports the pyriform lobe of the brain. The =dorsal border= joins the squamous temporal at the spheno-squamous suture. The =anterior border= joins the orbital wing. The =posterior border= forms the anterior boundary of the foramen lacerum; it presents =three notches=, which are (from within outward) the carotid, oval, and spinous (Incisura carotica, ovalis, spinosa). The angle of junction of the dorsal and posterior borders articulates with the parietal bone.

The =pterygoid processes= (Processus pterygoidei) arise from the temporal wings and the body. They project downward and forward, and curve outward at the lower part. The root is perforated by the =alar canal= (Canalis alaris),[11] which transmits the internal maxillary artery. From this canal a branch leads upward and forward to open at the temporal foramen. The =external surface= is concave, and is marked by lines for muscular attachment. The =internal surface= is largely concealed by the overlapping palate and pterygoid bones, with which it concurs in the formation of the =pterygoid= or =Vidian canal=.

=Development.=—The sphenoid is ossified in cartilage, and consists in early life of two distinct parts, the presphenoid and postsphenoid. The former develops from two centers, one in each wing; the latter has three centers, one for the body and one for each wing. The pterygoid processes ossify from the centers of the temporal wings.

=Variation.=—The dorsal border of the orbital wing may come to the surface through a defect in the frontal bone at the place where the horn process is situated in animals which have frontal horns.

THE ETHMOID BONE

The =ethmoid= (Os ethmoidale) is situated in front of the body and orbital wings of the sphenoid. It projects forward between the orbital plates of the frontal bones and enters into the formation of the cranial, nasal, and paranasal cavities.[12] It consists of four parts—the cribriform plate, two lateral masses, and the perpendicular plate.

The =cribriform plate= (Lamina cribrosa) is a sieve-like partition between the cranial and nasal cavities. Its margin joins the orbital wings of the sphenoid laterally, and the cranial plate of the frontal bones dorsally. Its =cranial surface= is divided into two parts by a median ridge, the =crista galli=, which is the intracranial portion of the perpendicular plate. Each half forms a deep oval cavity, the =ethmoidal= or =olfactory fossa=, which lodges the olfactory bulb. The plate is perforated by numerous small foramina for the passage of the olfactory nerve filaments, and on either side is the much larger =ethmoidal foramen.= The =nasal surface= is convex, and has the lateral masses attached to it.

The =lateral masses= or =labyrinth= project forward from the cribriform plate into the posterior part of the nasal cavity, which they nearly fill. Each mass is somewhat conical in shape, with the base attached to half of the cribriform plate. The =inner surface= is separated by a narrow space from the perpendicular plate. The =outer surface= is convex and faces chiefly into the frontal and maxillary sinuses, but is attached behind to the inner wall of the orbital cavity; it is covered by a very thin layer of bone, the =lamina papyracea.= The mass consists of a large number of delicate, scroll-like plates of bone, termed =ethmoturbinals= or =ethmoidal cells.= These are attached to the lamina papyracea, and are separated by narrow intervals termed =ethmoidal meatuses=, which communicate with the nasal cavity. In the living animal the ethmoturbinals are covered with mucous membrane.

[Illustration:

FIG. 29.—CROSS-SECTION OF LATERAL MASS OF ETHMOID BONE OF HORSE.]

The lateral mass is a very complex structure, the arrangement of which may be studied on cross-sections of decalcified specimens with the mucous membrane retained. Each mass consists of six turbinals which extend almost to the perpendicular plate and are termed =endoturbinals=. These diminish in size from above downward; the largest is attached to the nasal bone, and is hence usually called the naso-turbinal or superior turbinal; the second is much smaller, and is very commonly termed the great ethmoid cell. Between the endoturbinals are twenty-one small =ecto=turbinals, and all are beset with secondary and tertiary coiled lamellæ.

The =perpendicular plate= or =mesethmoid= (Lamina perpendicularis) is median, and forms the posterior part of the septum nasi. Its =lateral surfaces= are nearly plane, but are marked below by some grooves and ridges; they are covered by the nasal mucous membrane. The =anterior border= is irregular and is continuous with the septal cartilage. The =posterior border= projects into the cranial cavity as a ridge, the =crista galli.= The =dorsal border= joins the frontal bones at their line of junction—the frontal suture. The =ventral border= is received into the groove of the vomer.

=Development.=—The ethmoid develops in cartilage from five centers, two for each lateral mass, and one for the perpendicular plate; from the latter ossification extends into the cribriform plate. At birth the perpendicular and cribriform plates are entirely cartilaginous. By the time ossification is complete the ethmoid has united with surrounding bones to such an extent that it cannot be separated intact for study.

THE INTERPARIETAL BONE

This bone (Os interparietale) is centrally placed between the squamous part of the occipital and the parietal bones. It is usually described as a single bone, although it ossifies from two chief lateral centers, and is sometimes distinctly paired in skulls of young foals.

The =external surface= (Facies externa) is quadrilateral and is flat and smooth in the very young foal; later it presents the median external sagittal crest.

The =internal surface= (Facies cerebralis) presents the =internal occipital protuberance=, a three-sided process which projects downward and forward into the cranial cavity between the cerebral hemispheres and the cerebellum; it has three concave surfaces and three sharp borders which form part of the tentorium osseum.

The =posterior border= is thick; it joins the squamous part of the occipital bone. The =lateral= and =anterior borders= are united by suture with the parietal bones.

=Development.=—The interparietal ossifies in membrane from two chief lateral centers.[13] It fuses first with the parietals, somewhat later with the occipital, but the period at which this union takes place is quite variable.

THE PARIETAL BONES

The two =parietal bones= (Ossa parietalia) form the greater part of the roof of the cranium; they unite in the median line, forming the =sagittal suture=. Each is quadrilateral in outline and has two surfaces and four borders.

The =external surface= (Facies parietalis) is convex, and is marked by a more or less prominent curved line, the =external sagittal crest=; this is median in its posterior part, and is continuous with the crest of like name on the occipital bone; in front it curves outward and is continuous with the frontal crest. The surface external to the crest (Planum temporale) enters into the formation of the temporal fossa, and is roughened for the attachment of the temporal muscle.

The =internal= or =cerebral surface= (Facies cerebralis) is concave. It presents numerous =digital impressions= (Impressiones digitatæ) which correspond to the gyri of the cerebrum. There are also furrows (Sulci vasculosi) for the meningeal arteries. Along the inner border there is a =sagittal groove= (Sulcus sagittalis) for the superior longitudinal sinus.

The =anterior border= joins the frontal bone at the =parieto-frontal suture= (Sutura coronalis).

The =posterior border= meets the occipital bone at the =parieto-occipital suture= (Sutura lambdoidea). Below this junction it curves inward and concurs with the temporal bone in the formation of the =parieto-temporal canal= (Meatus temporalis). A =transverse groove= (Sulcus transversus) connects this canal with the sagittal sulcus.

The =internal border= is thick and serrated. It joins its fellow at the =sagittal suture=, and (in the young subject) meets the interparietal at the =interparietal suture=. The line of junction is marked internally by the =internal sagittal crest= (Crista sagittalis interna).

The =external border= is beveled and is overlapped by the squamous temporal bone, forming the parieto-temporal suture (Sutura parieto-squamosa). The angle of junction of the external and posterior borders articulates with the posterior angle of the temporal wing of the sphenoid.

=Development.=—Each parietal bone ossifies in membrane from a single center. In the young foal the central part of the bone is much more convex than in the adult and forms a prominence similar to the pronounced tuber parietale of the young child; the external sagittal crest is not present, and the external surface is smooth.

The sagittal suture is usually closed at four years, the parieto-occipital at five years, and the parieto-temporal at twelve to fifteen years.

THE FRONTAL BONES

The =frontal bones= (Ossa frontalia) are situated on the limits of the cranium and face, between the parietals behind and the nasal bones in front. Each is irregularly quadrilateral, and consists of frontal, orbital, and temporal parts.

The =frontal part= (Pars naso-frontalis) forms the basis of the forehead. Its =external surface= (Facies frontalis) is nearly flat, and is smooth and subcutaneous; it is separated from the temporal part by the external frontal crest (Crista frontalis externa). At the junction with the orbital part the =supraorbital= or =zygomatic process= (Proc. zygomaticus) curves outward and downward to join the zygomatic arch. The process partially separates the orbit from the temporal fossa; its root is perforated by the =supraorbital foramen=, or presents instead a notch on its anterior border; its upper surface is convex, while the lower or orbital surface is concave and smooth, forming a shallow fossa for the lacrimal gland (Fossa glandulæ lacrimalis). The =internal surface= enters into the formation of the cranial cavity and the frontal sinus. The cranial surface presents digital impressions for the cerebral gyri. The two plates of the bone separate and diverge in front, and thus inclose a large air-space which is part of the =frontal sinus=. The cranial plate curves downward and articulates with the cribriform plate of the ethmoid bone; the facial plate extends forward and joins the nasal and lacrimal bones.

The =orbital part= (Pars orbitalis) forms the major part of the inner wall of the orbital cavity. It is separated from the frontal part by a prominent ridge which is part of the orbital margin. Its =external= or =orbital surface= is concave and smooth, and presents superiorly a small depression (Fovea trochlearis), which is bridged by a small bar of cartilage, around which the superior oblique muscle of the eye is reflected. The lower border concurs with the orbital wing of the sphenoid in the formation of the ethmoidal or internal orbital foramen. The =internal surface= faces into the frontal sinus and gives attachment to the lateral mass of the ethmoid.

The =temporal part= is separated from the orbital part by the deep =sphenoidal notch= (Incisura sphenoidalis), which is occupied by the orbital wing of the sphenoid. Its =external surface= forms part of the inner wall of the temporal fossa. The =internal surface= is largely covered by the orbital wing of the sphenoid in the young subject, but later forms part of the wall of the frontal sinus.

The principal connections of the frontal bone are as follows: (1) The inner border joins its fellow at the =frontal suture=. (2) The anterior border meets the nasal and lacrimal at the =naso-frontal= and =fronto-lacrimal sutures=. (3) Laterally it forms the =spheno-frontal= suture with the orbital wing of the sphenoid, and also joins the palate bone and maxilla. (4) Posteriorly it meets the parietal at the =parieto-frontal= (or coronal) =suture=, and articulates below this with the squamous temporal. (5) The extremity of the supraorbital process unites with the zygomatic process of the temporal bone.

=Development.=—Each ossifies in membrane from one center which appears in the root of the supraorbital process. In the new-born foal there is a slit between the cranial plate and the orbital and temporal plates which receives the cartilaginous margin of the orbital wing of the sphenoid.

THE TEMPORAL BONES

The =temporal bone= (Os temporale) forms the greater part of the lateral wall of the cranium. It is situated between the occipital behind, the parietal above, the frontal in front, and the sphenoid below. It consists of two distinct parts, =squamous= and =petrous=.

1. The =squamous temporal= (Squama temporalis) is a shell-like plate which has two surfaces and four borders.

The =internal surface= (Facies cerebralis) is largely overlapped by the surrounding bones, but its central part is free and presents digital impressions and vascular grooves.

The =external surface= (Facies temporalis) is convex, and enters into the formation of the temporal fossa. From its lower part there springs the =zygomatic process= (Processus zygomaticus), which forms the external boundary of the temporal fossa. It is at first directed outward, and is wide and flattened dorso-ventrally. It then turns forward, becomes narrower, and is twisted so that its surfaces are internal and external. Its anterior end is pointed and joins the zygomatic process of the malar bone, with which it forms the =zygomatic arch= (Arcus zygomaticus). The narrow anterior part has a convex outer surface and a concave inner one. Its upper border has a rough area for articulation with the supraorbital process of the frontal. Its lower border is wide and rough. The wide posterior part presents on its ventral face a surface for articulation with the condyle of the mandible. This surface consists of a transversely elongated =condyle= (Tuberculum articulare), behind which is the =glenoid fossa= (Fossa mandibularis). The fossa is limited behind by the =postglenoid process=, the anterior surface of which is articular. Behind this process is a fossa in which is the external opening of the parieto-temporal canal. The dorsal surface is concave and forms the outer boundary of the temporal fossa. The superior border is sinuous and is continuous behind with the temporal crest.

The =posterior process= (Processus posterior) springs from the posterior part of the squama. Its external surface is crossed by the temporal crest, which forms here the outer limit of the temporal fossa. The internal surface forms the outer boundary of the parieto-temporal canal, and is elsewhere applied to the petrous portion. It divides into two branches, upper and lower; the upper branch unites with the occipital bone, while the lower one curves downward behind the external auditory process and overlaps the mastoid process.

The =superior border= of the squamous temporal articulates with the parietal, forming the =parieto-temporal suture=. The =inferior border= joins the temporal wing of the sphenoid at the =spheno-squamous suture=. The =anterior border= unites with the frontal bone, and the =posterior= with the parietal.

2. The =petrous temporal= (Os petrosum) is placed between the occipital behind and the parietal in front, and is largely overlapped externally by the squamous temporal. It has the form of a four-sided pyramid, the base of which is ventral.

The =external surface= is mainly concealed by the squamous temporal, but two features are visible. A short tube of bone, the =external auditory process=, protrudes from the lowest part through the notch of the squamous temporal. The process is directed outward, upward, and a little forward. It gives attachment to the annular cartilage of the ear. Its lumen, the =external auditory meatus= (Meatus acusticus externus), conducts to the cavity of the middle ear (tympanum) in the dry skull, but is separated from it by the tympanic membrane in the natural state. The =mastoid process= projects ventrally in the interval between the posterior process of the squamous temporal and the root of the paramastoid (or styloid) process of the occipital bone; its outer surface is crossed by a curved groove which leads to the parieto-temporal canal.

The =internal surface= faces into the cerebellar fossa of the cranium. It is concave and smooth but irregular. In its lower part is the entrance to a short canal, the =internal auditory meatus=, which transmits the seventh and eighth cranial nerves.

The fundus of the meatus is divided by a crest into a superior and an inferior fossa. In the superior one is the origin of the =facial canal=, which curves through the bone and opens externally at the stylo-mastoid foramen; it transmits the facial (seventh cranial) nerve. The inferior fossa presents small foramina for the passage of fibers of the auditory (eighth cranial) nerve.

Behind the meatus and near the posterior margin of the surface is the slit-like opening of the aquæductus vestibuli, covered by a scale of bone. Below this is a narrow fissure, the orifice of the aquæductus cochleæ.

The =anterior surface= looks upward and forward. The outer part articulates with the parietal bone and the inner part faces into the cerebral fossa of the cranium. A sharp border, the =petrosal crest= (Crista petrosa), separates this surface from the inner one.

The =posterior surface= joins the lateral part of the occipital bone.

The =base forms= the outer boundary of the foramen lacerum basis cranii. It is very irregular and presents a number of important features. The =hyoid process= is a short rod which projects downward and forward below the base of the external auditory process, inclosed in a bony tube; it is connected by a bar of cartilage with the hyoid bone. The =stylo-mastoid foramen= is situated between the root of the hyoid process and the mastoid process; it is the external opening of the facial canal, through which the facial nerve emerges. The =bulla ossea= is a considerable eminence situated centrally; it is thin-walled and incloses a cavity which is part of the tympanum. The =muscular process=[14] is a sharp spine which projects downward and forward from the anterior part of the base; it gives origin to the tensor and levator palati muscles. External to the root of the preceding is the small =petro-tympanic= or =Glaserian fissure= (Fissura petro-tympanica) for the passage of the chorda tympani nerve. The osseous =Eustachian tube= is a semicanal at the inner side of the root of the muscular process; it leads to the tympanum. At the inner side of the preceding is the slit-like orifice of the petrosal canal, which communicates with the facial canal.

The =apex= projects upward and backward between the squamous temporal and the occipital bone.

=Development.=—The petrous temporal may be regarded as consisting of petro-mastoid and tympanic parts. The latter includes the external auditory process, the bulla ossea, and the muscular process; it is developed in membrane. The petro-mastoid is developed in the cartilaginous ear capsule. Its petrous part consists of very dense bone which contains the labyrinth or internal ear and forms the inner wall of the tympanum.

The =parieto-temporal canal= (Meatus temporalis) is a continuation of the transverse groove which extends outward from the base of the tentorium osseum. It is directed downward, forward, and somewhat outward, and opens externally in front of the root of the auditory process. It is bounded by the squamous temporal externally, the petrous behind, and the parietal in front and internally. Several foramina open from it into the temporal fossa. It contains a large vein (Vena cerebralis dorsalis), the continuation of the transverse sinus of the dura mater.

The =foramen lacerum basis cranii= (Foramen lacerum et jugulare) is a large irregular opening in the cranial base, bounded internally by the basilar part of the occipital bone, externally by the petrous temporal, and in front by the temporal wing of the sphenoid. It consists of a large anterior part (Foramen lacerum anterius), and a narrow posterior part (Foramen lacerum posterius s. jugulare). It transmits the internal carotid artery, the middle meningeal artery, the mandibular, ninth, tenth, and eleventh cranial nerves, and the inferior cerebral vein.

In the fresh state the foramen is occupied by a dense fibrous membrane which is perforated by apertures for the various structures transmitted. Thus there are three openings in front for the internal carotid artery, the mandibular nerve, and the middle meningeal artery; these are (from within outward) the foramen caroticum, ovale, spinosum.

(B) BONES OF THE FACE

The bones of the face (Ossa faciei) are the Maxilla, Premaxilla, Palatine, Pterygoid, Nasal, Lacrimal, Malar, Superior Turbinal, Inferior Turbinal, Vomer, Mandible, and Hyoid. The last three are single, the others paired.

THE MAXILLAE

The =maxillæ= are the principal bones of the upper jaw and carry the upper cheek teeth. They are situated on the lateral aspect of the face, and articulate with almost all of the facial bones and the frontal and temporal also. For description each may be divided into a body and two processes.

The =body= (Corpus maxillæ) presents two surfaces, two borders, and two extremities. The =external= or =facial surface= (Facies lateralis) is somewhat concave in front and convex behind. On its posterior part is a horizontal ridge, the =facial= or =zygomatic crest= (Crista facialis); in a skull of medium size its anterior end is about an inch and a half (3 to 4 cm.) above the third or fourth cheek tooth, and it is continued behind by a corresponding ridge on the malar bone. About two inches (5 cm.) above and a little in front of the anterior end of the crest is the =infraorbital foramen= (Foramen infraorbitale); this is the external opening of the infraorbital canal.

In the young horse the anterior part of the surface is convex over the embedded parts of the teeth. As the latter are extruded the surface flattens and becomes concave in old subjects.

The =internal= or =nasal surface= (Facies nasalis) is concave dorso-ventrally; it forms the greater part of the lateral wall of the nasal cavity. Its upper part is crossed obliquely forward and downward by the shallow =lacrimal groove= (Sulcus lacrimalis), which contains the naso-lacrimal duct; in the adult the posterior part of the groove is converted into a canal, which is continuous with that on the inner surface of the lacrimal bone. Below the groove is the =inferior turbinal crest= (Crista conchalis inferior), to which the inferior turbinal bone is attached. Lower down and parallel with the turbinal crest is the =palatine process=, which projects inward like a shelf. Behind this the surface is rough for articulation with the palate bone; this area is crossed by a groove which concurs with a furrow on the palate bone in the formation of the =palatine canal=. The posterior part of the bone is excavated to form part of the maxillary sinus.

The =superior border= is irregular and scaly. Its anterior part is grooved and its posterior part beveled for articulation with the nasal process of the premaxilla and the nasal and lacrimal bones.

The =inferior= or =alveolar border= (Processus alveolaris) is thick, and presents six large cavities, the =alveoli=, for the cheek teeth. The alveoli are separated by transverse =interalveolar septa=. There is often a small alveolus for the first premolar (“wolf tooth”) close to the first large one. Further forward the border is narrow and forms part of the =interdental= or =interalveolar space= (Margo interalveolaris). Behind the last alveolus is a rough area, the =alveolar tuberosity=.

The =anterior extremity= is pointed. It joins the premaxilla, and forms with it the alveolus for the canine tooth.

The =posterior extremity= forms a rounded prominence, the =maxillary tuberosity= (Tuber maxillare). Internal to the tuberosity is a deep cavity, the maxillary hiatus, in which are three foramina. The upper one, the =maxillary foramen=, leads into the infraorbital canal. The lower one, the =posterior palatine foramen=, is the entrance to the palatine canal. The =sphenopalatine foramen= perforates the inner wall of the hiatus and opens into the nasal cavity.

The =zygomatic= or =temporal process= (Processus temporalis) projects backward above and external to the tuberosity; it is overlapped by the corresponding part of the malar and also articulates with the zygomatic process of the temporal. A small curved plate extends inward from it and joins the frontal and palate bones, forming part of the floor of the orbit.

The =palatine process= (Processus palatinus) is a plate which projects horizontally inward from the lower part of the inner surface of the body. It forms the greater part of the basis of the hard palate. Its =superior= or =nasal surface= is smooth and concave transversely; on its anterior part, close to the inner border, is a shallow groove in which the organ of Jacobson is situated. The inferior or =palatine surface= is slightly concave from side to side, and presents along its outer part the =palatine groove= (Sulcus palatinus). The groove is a continuation of the palatine canal, and contains the palatine artery and nerve. The =internal border= unites with its fellow to form the median palatine suture; its nasal aspect bears the nasal crest, which forms, with that of the opposite process, a groove for the vomer. The =posterior border= unites with the horizontal part of the palate bone at the

transverse palatine suture.

[Illustration:

FIG. 31.—UPPER JAW OF HORSE ABOUT FOUR AND A HALF YEARS OLD, VENTRAL VIEW.

1, 1, Posterior nares; 2, vomer; 3, horizontal part of palate bone; 4, anterior palatine foramen; 5, palatine groove; 6, transverse palatine suture; 7, median palatine suture; 8, palate process of maxilla; 9, palate process of premaxilla; 10, foramen incisivum; 11, malar bone; 12, maxilla; 13, anterior end of facial crest; 14, interalveolar space; I. 1–3, incisor teeth; _C_, canine tooth; _P1_, first premolar or “wolf” tooth.]

The =infraorbital= or =superior dental canal= extends almost horizontally from the maxillary foramen to the infraorbital foramen. It is placed at the upper edge of the inner plate of the maxilla, and traverses the maxillary sinus. Near the infraorbital foramen it gives off a small canal (Canalis alveolaris incisivus) which lies above the roots of the premolars and extends also into the premaxilla, carrying vessels and nerves to the teeth there.

=Development.=—The maxilla ossifies in membrane below and external to the cartilaginous nasal capsule. It has one chief center and a supplementary one in the region of the deciduous canine tooth (Martin).

THE PREMAXILLAE

The =premaxillæ= (Ossa incisiva) form the anterior part of the upper jaw and carry the incisor teeth. Each consists of a body and two processes, nasal and palatine.

The =body= is the thick anterior part which carries the incisor teeth. Its =labial= or =superior= surface is convex and smooth, and is related to the upper lip. The =palatine= or =inferior surface= is concave and presents a foramen a little behind its middle.[15] The =internal surface= is rough, and joins the opposite bone; it is marked by a curved groove, which forms with that on the opposed surface, the incisive =foramen= (Foramen incisivum). The =alveolar border= (Limbus alveolaris) separates the palatine and labial surfaces; it is curved and thick, and presents three alveoli for the incisor teeth; behind the third alveolus it is rounded and free, forming part of the =interalveolar space=.

The =nasal process= (Processus nasalis) projects backward and upward from the body, forming here the lateral wall of the nasal cavity. The two =surfaces=, =facial= and =nasal=, are smooth and rounded. The =superior border= is free, thick, and smooth. The =inferior border= is dentated and joins the maxilla; at its anterior end it forms with the latter the alveolus for the permanent canine tooth.[16] The =posterior extremity= fits into the interval between the nasal bone and the maxilla.

The =palatine process= (Processus palatinus) is a thin plate which forms the anterior part of the basis of the hard palate. Its =nasal= or =superior surface= has a longitudinal ridge which forms with that of the other side a groove for the septal cartilage. The =palatine= or =inferior surface= is flat. The =internal border= is serrated and meets its fellow at the median palatine suture. The =external border= is separated from the maxilla and the nasal process by the =palatine cleft= (Fissura palatina). The =posterior extremity= fits into the interval between the vomer and the palatine process of the maxilla.

=Development.=—The premaxilla ossifies from a single center. Fusion of the two bones is complete at the end of the third or the beginning of the fourth year.

THE PALATINE BONES

The =palatine bones= (Ossa palatina) are situated on either side of the posterior nares, and form the posterior margin of the hard palate. Each is twisted so as to form a horizontal and a perpendicular part.

The =horizontal part= (Pars horizontalis) is a narrow plate which forms the posterior part of the hard palate. It presents smooth =nasal= and =palatine surfaces=. The =internal border= meets its fellow at the median palatine suture, on the nasal aspect of which is the nasal crest. The =anterior border= joins the palate process of the maxilla at the transverse palatine suture, and forms with it the anterior palatine foramen. The =posterior border= is concave and free; it gives attachment to the aponeurosis of the soft palate.

The =perpendicular part= (Pars perpendicularis) is more extensive and forms the outer boundary of the posterior nares. The =nasal= or =internal surface= is in the greater part of its extent concave and smooth; it is marked by a narrow rough area to which the pterygoid bone is attached. Below this the bone curves outward, forming the pterygoid process. The =maxillary= or =external

surface= (Facies maxillaris) presents three areas for consideration. The largest articulates with the maxilla; it is rough and is crossed by a groove which enters into the formation of the palatine canal. Behind this is a smooth part which assists in forming the =pterygo-palatine fossa=. The rough area below this is overlapped by the pterygoid process of the sphenoid bone. The =superior border= is perforated by the =sphenopalatine foramen=. Behind the foramen the two plates of the bone separate to inclose part of the =sphenopalatine sinus=. The inner plate curves inward to articulate with the vomer. The outer plate joins the maxilla and frontal and the orbital wing of the sphenoid.

=Development.=—The palatine bone ossifies in membrane from a single center.

THE PTERYGOID BONES

The =pterygoid bones= (Ossa pterygoidea) are narrow, thin, bent plates, situated on either side of the posterior nares. Each has two surfaces and two extremities. The =internal surface= is smooth, and forms part of the boundary of the posterior nares. The =external surface= articulates with the palatine, vomer, and sphenoid, concurring with the last in the formation of the =pterygoid= or =Vidian canal=. The =anterior extremity= is free, turned slightly outward, and forms the =hamulus=, a pulley around which the tendon of the tensor palati muscle is reflected.

=Development.=—The pterygoid ossifies in membrane from a single center.

THE NASAL BONES

The =nasal bones= (Ossa nasalia) are situated in front of the frontal bones and form the greater part of the roof of the nasal cavity. They have an elongated triangular outline, wide behind, pointed in front. Each presents two surfaces, two borders, a base, and an apex.

The =external= or =facial surface= is smooth and is convex transversely; the profile contour is usually slightly wavy, with a depression about its middle and a variably prominent area in front.

The =internal= or =nasal surface= is smooth and concave from side to side. About in its middle it presents the =superior turbinal crest= (Crista conchalis dorsalis), which is parallel with the inner border, and has the superior turbinal bone attached to it. Most of this surface faces into the nasal cavity, but its posterior part enters into the formation of the frontal sinus; the latter area is marked off by an oblique ridge.

The =internal border= is straight, and meets the opposite bone at the =nasal suture=.

The =external border= is irregular. Its anterior third is free and concurs with the nasal process in forming the =naso-maxillary notch= (Incisura naso-maxillaris). Behind this it is scaly for articulation with the end of the nasal process, the maxilla, and the lacrimal, forming the =naso-maxillary= and =naso-lacrimal sutures=.

The =base= or posterior end is beveled and overlaps the frontal bone, forming the =naso-frontal suture=.

The =apex= is pointed and thin.

=Development.=—Each nasal bone ossifies in membrane from a single center. The nasal suture does not close completely even in old age. In some cases the two plates separate to inclose a small air-space in the posterior part.

THE LACRIMAL BONES

The =lacrimal bones= (Ossa lacrimalia) are situated at the anterior part of the orbit, and extend forward on the face to the posterior border of the maxilla. Each presents three surfaces and a circumference.

The external aspect is clearly divided into orbital and facial parts by the orbital margin. The =orbital surface= (Facies orbitalis) is triangular in outline, smooth and concave; it forms part of the inner and front wall of the orbit. Near the orbital margin it presents a funnel-like =fossa= for the lacrimal sac (Fossa sacci lacrimalis), which is the entrance to the osseous lacrimal canal. Behind this is a depression in which the inferior oblique muscle of the eye takes origin. The =facial surface= (Facies facialis) is more extensive, and has the form of an irregular pentagon. It is slightly convex and smooth in the foal, flattened in the adult. It usually bears the small =lacrimal tubercle=, situated nearly an inch (ca. 2 cm.) from the orbital margin.

The =nasal= or =internal surface= (Facies nasalis) faces into the frontal and maxillary sinuses. It is concave and very irregular, and is crossed almost horizontally by the =osseous lacrimal canal= (Canalis lacrimalis osseus).

The =orbital margin= (Margo orbitalis) is concave, rough above, smooth below.

The =circumference= articulates above with the frontal and nasal bones, below with the malar and maxilla, in front with the maxilla, and behind with the frontal. The various sutures so formed are designated by combinations of the names of the bones.

=Development.=—Each ossifies in membrane from a single center.

THE MALAR BONES

The =malar= or =zygomatic bones= (Ossa zygomatica) are placed between the lacrimal above and the maxilla below and in front. Each is irregularly triangular in outline and presents three surfaces, three borders, a base, and an apex.

The =facial surface= is smooth, slightly convex, wide in front, and narrow behind. At its lower part it presents the =facial= or =zygomatic crest=, which is continuous in front with the similar ridge on the maxilla and behind with the zygomatic process of the temporal; the crest is rough below, where the masseter muscle is attached to it.

The =orbital surface= is separated from the facial surface by the concave =orbital margin=. It is concave and smooth, and forms part of the lower and front wall of the orbit.

The =nasal surface= is concave and faces into the maxillary sinus. In the young foal a considerable part of it articulates with the maxilla.

The =superior border= articulates with the lacrimal chiefly, but to a small extent behind with the maxilla also.

The =inferior border= and the =base= articulate with the maxilla.

The =apex= is beveled above and is overlapped by the zygomatic process of the temporal bone.

=Development.=—Each ossifies in membrane from one or two centers.

THE TURBINAL BONES

These (Ossa turbinata) are delicate, scroll-like bones, four in number, which are attached to the lateral walls of the nasal cavity. They project into the cavity and greatly diminish its extent. Each is composed of a very thin lamina, cribriform in many places, and covered on both sides with mucous membrane in the fresh state. They are arranged in two pairs, superior and inferior.

The =superior= or =naso-turbinal= (Concha dorsalis)[17] is somewhat cylindrical in form, small at its anterior part, and flattened transversely. It is attached to the turbinal crest of the nasal bone and the nasal plate of the frontal bone. The anterior part is rolled like a scroll one and a half times, thus inclosing a cavity which communicates with the middle meatus nasi. The arrangement is best seen on a cross-section (Fig. 37). The posterior part is not rolled, but its lower border is attached to the lateral nasal wall, thus helping to inclose a large space which is part of the frontal sinus. This cavity is separated from that of the scroll-like part by a transverse septum. The =internal surface= is flattened, and is separated from the septum nasi by a narrow interval, the =common meatus= (Meatus nasi communis). Another narrow passage, the =superior meatus= (Meatus nasi superior), separates the upper surface from the roof of the nasal cavity. The space between the lower surface and the inferior turbinal is the =middle meatus= (Meatus nasi medius). The anterior extremity is prolonged toward the nostril by two small bars of cartilage.

The =inferior= or =maxillo-turbinal bone= (Concha ventralis) is shorter and smaller posteriorly than the upper one. It is attached to the inferior turbinal crest, and consists, like the upper one, of an anterior coiled and a posterior uncoiled portion.

To express briefly the mode of coiling of the two bones of the same side we may say that they are rolled toward the septum and each other.

The inferior and posterior borders of the posterior part are attached to the maxilla, thus helping to inclose a cavity which is part of the maxillary sinus. The lower surface is separated from the floor of the nasal cavity by the =inferior meatus= (Meatus nasi inferior), which is much larger than the other nasal passages. The anterior extremity is prolonged to the nostril by a curved bar of cartilage.

=Development.=—Each ossifies in cartilage from a single center.

THE VOMER

The =vomer= is a median unpaired bone, which assists in forming the lower part of the septum nasi. It is composed of a thin lamina which is bent (except in its posterior part) so as to form a narrow groove (Sulcus septi narium), in which the lower part of the perpendicular plate of the ethmoid bone and the septal cartilage are received. The =lateral surfaces=, right and left, are highest near the posterior end and diminish gradually to the anterior end; they are slightly convex dorso-ventrally, and are covered by the nasal mucous membrane during life. The =inferior border= is thin and free in its posterior third, and divides the posterior nares into right and left halves; in the remainder of its extent it is wider and is attached to the nasal crest. The =anterior extremity= lies above the ends of the palatine processes of the premaxillæ. The =posterior extremity= consists of two =wings= (Alæ vomeris) which extend outward below the body of the presphenoid; posteriorly they form a notch (Incisura vomeris), and laterally join the palate and pterygoid bones.

=Development.=—The vomer is primitively double, and ossifies from a center on either side in the membrane covering the cartilaginous septum nasi; the two laminæ then fuse below and form a groove.

THE MANDIBLE

The =mandible= or =inferior maxilla= (Mandibula) is the largest and the only movable bone of the face. The two halves of which it consists at birth unite during the second or third month, and it is usually described as a single bone. It carries the lower teeth, and articulates by its condyles with the squamous temporal on either side. It consists of a body and two rami.[18]

The =body= (Corpus mandibulæ) is the thick anterior part which bears the incisor teeth. It presents two surfaces and a border. The =lingual= or =superior surface= (Facies lingualis) is smooth and slightly concave; during life it is covered by mucous membrane, and the tip of the tongue overlies it. The =labial= or =mental surface= (Facies mentalis) is convex and is related to the lower lip. It is marked by a median furrow which indicates the position of the primitive symphysis mandibulæ. The curved =alveolar border= (Limbus alveolaris) presents six alveoli for the incisor teeth, and a little further back two alveoli for the canine teeth in the male; in the mare the latter are usually absent or small.

The =rami= (Rami mandibulæ) extend backward from the body and diverge to inclose the =submaxillary space= (Spatium mandibulare). Each ramus is bent so as to consist of a horizontal part (Pars molaris) which bears the lower cheek teeth, and a vertical part (Ramus mandibulæ) which is expanded and furnishes attachment to powerful muscles; the term =angle= is applied to the most prominent part of the curve. The ramus presents two surfaces, two borders, and two extremities. The =external surface= is smooth and slightly convex from edge to edge on the horizontal part; at the junction with the body it presents the =mental foramen= (Foramen mentale), which is the external opening of the mandibular or inferior dental canal. On the vertical part it is somewhat concave and presents a number of rough lines for the attachment of the masseter muscle. The =internal surface= of the horizontal part is smooth, and presents a shallow longitudinal depression in its middle; above this there is often a faint mylo-hyoid line for the attachment of the muscle of like name. At the lower part of the junction with the body there is a small fossa for the attachment of the genio-hyoid and genio-glossus muscles. On the vertical part the surface is concave, and is marked in its lower and posterior part by rough lines for the attachment of the internal pterygoid muscle. In front of its middle is the =mandibular= or =inferior maxillary foramen= (Foramen mandibulare), which is the posterior orifice of the =mandibular= or =inferior dental canal= (Canalis mandibulæ). The canal curves downward and passes forward below the cheek teeth, opening externally at the mental foramen; it is continued into the body of the bone as a small canal (Canalis alveolaris incisivus), which carries the vessels and nerves to the incisor teeth. The =superior= or =alveolar border= forms anteriorly part of the interalveolar space; here it is thin. Behind this it is thick and is excavated by six alveoli for the lower cheek teeth. Behind the last alveolus it curves sharply upward and is narrow and rough. In the young foal there is commonly a small alveolus for the vestige of the first premolar (“wolf tooth”) close to the first large one. The =inferior border= of the horizontal part is nearly straight; it is thick and rounded in the young horse, becoming narrower and sharp in old subjects. At its posterior part there is a smooth impression (Incisura vasorum) where the facial vessels and parotid duct turn round the bone. Behind this point the border curves sharply upward, forming the =angle= (Angulus mandibulæ); this part is thick and has two roughened lips, internal and external, separated by a considerable intermediate space; near the condyle it becomes narrower. The =anterior extremity= joins the body. The =superior extremity= comprises the =coronoid process= in front and the =condyle= behind, the two being separated by the =sigmoid notch= (Incisura mandibulæ), through which the nerve to the masseter muscle passes. The =coronoid process= (Processus coronoideus) is thin transversely and curved slightly

inward and backward. It projects upward in the temporal fossa, and furnishes insertion to the temporal muscle. The =condyle= (Capitulum mandibulæ) lies at a much lower level than the end of the coronoid process. It is elongated transversely and articulates with the squamous temporal through the medium of an articular disc. The part below the condyle is usually termed the =neck= (Collum mandibulæ); on its antero-internal part is a depression (Fovea pterygoidea) for the attachment of the external pterygoid muscle. The middle of the vertical part of the ramus consists to a large extent of a single plate of compact substance which may be so thin in places as to be translucent.

=Development.=—The mandible develops from two chief centers in the connective tissue which overlies the paired Meckel's cartilages. At birth it consists of two symmetrical halves which meet at a median symphysis. Fusion usually occurs in the second or third month.

=Age changes.=—These are associated largely with the growth and later with the reduction of the teeth. In the young horse, in which the teeth are large and are in great part embedded in the bone, the body is thick and strongly curved, and the horizontal part of the ramus is also thick. Later, as the teeth are extruded from the bone, the body becomes flattened and narrower, and the horizontal part of the ramus is thinner, especially in its lower part; the angle and the impression in front of it are more pronounced.

THE HYOID BONE

The =hyoid bone= (Os hyoideum) is situated chiefly between the vertical parts of the rami of the mandible, but its upper part extends somewhat further back. It is attached to the petrous temporal bones by rods of cartilage, and supports the root of the tongue, the pharynx, and larynx. It consists of a body, a lingual process, and three pairs of cornua.

The =body= or =basihyoid= (Basis ossishyoidei) is a short transverse bar, compressed dorso-ventrally. The upper surface is concave and smooth in its middle, and presents at each end a convex facet or tubercle for articulation with the small cornu. The lower surface is slightly roughened for muscular attachment. The anterior border carries medially the lingual process. The posterior border is concave and smooth in its middle, and carries on either side the thyroid cornu. The body, the lingual process, and the thyroid processes are fused together, and may be compared to a spur or a fork with a very short handle.

The =lingual process= (Processus lingualis) projects forward medially from the body, and is embedded in the root of the tongue during life. It is compressed laterally and has a blunt-pointed free end. The lateral surfaces are slightly concave. The upper border is narrow, the lower thick and irregular.

The =thyroid cornua= or =thyrohyoids= (Cornua laryngea)[19] extend backward and upward from the lateral parts of the body. They are compressed laterally (except at their junction with the body), and their posterior ends are connected with the anterior cornua of the thyroid cartilage of the larynx.

The =small cornua= or =keratohyoids= (Cornua minora) are short rods which are directed upward and forward from either end of the upper surface of the body. Each is somewhat constricted in its middle part and has slightly enlarged ends. The lower end has a small concave facet which articulates with the body. The upper end articulates with the great cornu, or with the middle cornu when present.

[Illustration:

FIG. 32.—HYOID BONE OF HORSE, VIEWED FROM THE SIDE AND SOMEWHAT FROM IN FRONT.

_a_, Body; _b_, lingual process; _c_, thyroid cornu; _c′_, cartilage of _c_; _d_, small cornu; _e_, middle cornu; _f_, great cornu; _f′_, muscular angle of great cornu; _g_, cartilage of great cornu. (Ellenberger-Baum, Anat. d. Haustiere.)]

The =great cornua= or =stylohyoids= are much the largest parts of the bone. They are directed upward and backward, and are connected above with the base of the petrous temporal bones. Each is a thin plate, seven or eight inches (ca. 18 to 20 cm.) long, which is slightly curved in its length, so that the external surface is concave and smooth. The internal surface is convex and smooth. The borders are thin. The upper extremity is large and forms two angles; the upper angle is connected by a rod of cartilage with the hyoid process of the petrous temporal bone; the lower angle is somewhat thickened and rough for muscular attachment. The lower extremity is small, and articulates with the small or the middle cornu.

The =middle cornua= or =epihyoids= are small wedge-shaped pieces or nodules interposed between the small and great cornua. They are usually transitory, and unite with the great cornua in the adult.

=Development.=—The hyoid ossifies in the cartilages of the second and third visceral arches. Each part has a separate center, except the lingual process, which ossifies by extension from the body. The latter has primarily two centers (Martin).

THE SKULL AS A WHOLE

The skull of the horse has the form of a long four-sided pyramid, the base of which is posterior. It is convenient to exclude the mandible and hyoid from present consideration. The division between the cranium (Cranium cerebrale) and the face (Cranium viscerale) may be indicated approximately by a transverse plane through the anterior margins of the orbits.

The =superior= or =frontal surface= (Norma frontalis) is formed by the upper part of the occipital, the interparietal, parietal, frontal, and nasal bones. It may be divided into parietal, frontal, nasal, and premaxillary regions. The parietal region extends from the occipital crest to the parieto-frontal or coronal suture. It is marked medially by the =external sagittal crest=, which bifurcates in front, the branches becoming continuous with the =frontal crests=. The latter curve outward to the root of the supraorbital process. The =frontal region= is the widest part of the surface, and is smooth and almost flat. It is bounded in front by the naso-frontal suture. On either side of it is the root of the =supraorbital process=, pierced by the =supraorbital foramen=. The =nasal region= is convex from side to side, wide behind, narrow in front. Its profile is in some cases nearly straight; in others it is undulating, with a variably marked depression about its middle and at the anterior end. The =premaxillary region= presents the =osseous nasal aperture= (Apertura nasalis ossea) and the =foramen incisivum=.

[Illustration:

The =lateral surface= (Norma lateralis) may be divided into cranial, orbital, and maxillary or preorbital regions.

The =cranial region= presents the temporal fossa, the zygomatic arch, and the outer part of the petrous temporal bone.

The =temporal fossa= is bounded internally by the sagittal and frontal crests, externally by the temporal crest and the zygomatic arch, and behind by the occipital crest. Its upper and middle parts are rough for the attachment of the temporal muscle. In its lower posterior part are several =foramina= which communicate with the parieto-temporal canal. The fossa is continuous in front with the orbital cavity.

The =zygomatic arch= is formed by the zygomatic processes of the temporal, malar, and maxilla. Its ventral face presents the =condyle= and =glenoid cavity= for articulation with the lower jaw, through the medium of the articular disc. Behind the glenoid cavity is the =postglenoid process=.

The =external auditory process= projects outward through a deep notch in the lower margin of the squamous temporal below the temporal crest. A little further back is the =mastoid process=, crossed in its upper part by a groove for the mastoid artery.

The =orbital region= comprises the orbit and the pterygo-palatine =fossa=.

The =orbit= is a cavity which incloses the eyeball, with the muscles, vessels, and nerves associated with it. It is not separated in the skeleton from the temporal fossa. The =long axis= of the cavity, taken from the optic foramen to the middle of the =inlet=, is directed forward, outward, and slightly upward. The =inner wall= (Paries medialis) is complete and extensive. It is concave and

smooth, and is formed by the frontal and lacrimal and the orbital wing of the sphenoid. In its extreme anterior part is the fossa for the lacrimal sac. Behind this is a small depression in which the inferior oblique muscle of the eye arises; here the plate which separates the orbit from the maxillary sinus is very thin. The =upper wall= (Paries superior) is formed by the frontal and to a small extent by the lacrimal bone. It presents the supraorbital foramen, which perforates the root of the supraorbital process. The =lower wall= (Paries inferior) is very incomplete, and is formed by the malar, the zygomatic process of the temporal, and to a small extent by the maxilla. The =external boundary= (Paries lateralis) is the supraorbital process. At the extreme posterior part is the =orbital group of foramina=. Four are situated in front of the pterygoid crest. Of these, the uppermost is the =ethmoidal= or =internal orbital foramen=, which transmits the ethmoidal vessels and nerve. The =optic foramen= is situated a little lower and further back; it transmits the optic nerve. Immediately below the optic is the =foramen lacerum orbitale=, which transmits the ophthalmic, third, sixth, and sometimes the fourth nerve; commonly there is a very small =trochlear= or =pathetic foramen= in the crest for the last-named nerve. The =foramen rotundum= is below the foramen lacerum, from which it is separated by a thin plate; it transmits the superior maxillary nerve. The =alar canal= opens in common with the foramen rotundum, and the anterior opening of the pterygoid or Vidian canal is also found here. The =temporal foramen= (For. alare parvum) is just behind the pterygoid crest and on a level with the foramen lacerum. It is the upper opening of a canal which leads from the alar canal, and through it the anterior deep temporal artery emerges. The =inlet= of the orbital cavity (Aditus orbitæ) is circumscribed by a complete bony ring, which is nearly circular. Its antero-inferior part (Margo infraorbitalis) is smooth and rounded; the remainder (Margo supraorbitalis) is rough and irregularly notched. During life the cavity is completed by the periorbita or ocular sheath, a conical fibrous membrane, the apex of which is attached around the optic foramen.

Below the orbital cavity is the =pterygo-palatine fossa=. Its wall is formed by the pterygoid process, the perpendicular part of the palate bone, and the tuber maxillare. Its deep anterior part (maxillary hiatus) contains three foramina. The upper one, the =maxillary foramen=, is the entrance to the infraorbital canal, which transmits the infraorbital nerve and vessels. The =sphenopalatine foramen= transmits vessels and nerves of like name to the nasal cavity. The lower foramen, the =posterior palatine=, transmits the palatine artery and nerve to the palatine canal. The upper part of the fossa is smooth, and is crossed by the internal maxillary artery and the maxillary nerve. The lower part is chiefly roughened for the attachment of the internal pterygoid muscle, but is crossed in front by a smooth groove in which the palatine vein lies.

The =maxillary= or =preorbital region= is formed chiefly by the maxilla, but also by the premaxilla, and the facial parts of the lacrimal and malar bones. Its contour is approximately triangular, the base being posterior. It offers two principal features. The =facial crest= extends forward from the lower margin of the orbit, and ends abruptly at a point about an inch and a half (3 to 4 cm.) above the third or fourth cheek tooth;[20] its inferior aspect is rough for the attachment of the masseter muscle. The =infraorbital foramen= is situated in a transverse plane about an inch (ca. 2 to 3 cm.) in front of the end of the crest and about two inches (5 cm.) above it. The foramen opens forward, and through it the infraorbital artery and nerve emerge. The surface over the premolar teeth varies greatly with age, in conformity with the size of the embedded parts of the teeth. In the young horse the surface here is strongly convex, the outer plate of bone is thin and even defective sometimes in places, and the form of the teeth is indicated by eminences (Juga alveolaria). In the old animal the surface is concave on account of the extrusion of the teeth from the bone. The downward curve of the premaxilla is pronounced in the young subject, very slight in the aged.

The =inferior= or =basal surface= (Norma basalis), exclusive of the mandible, consists of cranial, guttural, and palatine regions.

The =cranial region= (Basis cranii externa) extends forward to the vomer and pterygoid processes (Fig. 28). At its posterior end is the =foramen magnum=, flanked by the =occipital condyles=. External to the latter is the =condyloid fossa=, in which is the =hypoglossal foramen=, which transmits the hypoglossal nerve and the condyloid artery and vein. Further outward are the =paramastoid= or =styloid processes= (Processus jugulares) of the occipital bone. Extending forward centrally is a prismatic bar, formed by the basilar part of the occipital and the body of the sphenoid bone; at the junction of these parts are tubercles for the attachment of the ventral straight muscles of the head. On either side of the basilar part of the occipital is the =foramen lacerum basis cranii=, bounded externally by the base of the petrous temporal bone. In front of these the region becomes very wide on account of the lateral extension of the =zygomatic processes=, bearing on the ventral aspect the =condyle= and =glenoid cavity= for articulation with the mandible. Beyond this the process turns forward and joins the =zygomatic process= of the malar, completing the zygomatic arch and the surface for the attachment of the masseter muscle. On either side of the body of the sphenoid is the infratemporal fossa, formed by the temporal wing and the root of the pterygoid process of the sphenoid bone. It is bounded in front by the pterygoid crest, which separates it from the orbit and the pterygo-palatine fossa. In it is the =pterygoid= or =alar foramen=, which transmits the internal maxillary artery. A little lower is the entrance to the pterygoid (Vidian) =canal=.

The =guttural region= presents the pharyngeal orifice of the nasal cavity. This is elliptical and is divided in its depth medially by the vomer into two =posterior nares= or =choanæ=. It is bounded in front and laterally by the palate and pterygoid bones, behind by the vomer. It is flanked by the hamular process of the pterygoid bones. The plane of the opening is nearly horizontal, and the length is about twice the width.

The =palatine region= comprises a little more than half of the entire length of the base of the skull (Fig. 31). The =hard palate= (Palatum durum) is concave from side to side, and in its length also in the anterior part. It is formed by the palatine processes of the premaxillæ and maxillæ, and the horizontal parts of the palate bones. It is circumscribed in front and laterally by the =superior alveolar arch=, in which the upper teeth are implanted. The =interalveolar space= (Margo interalveolaris) is that part of the arch in which alveoli are not present. Behind the last alveolus is the =alveolar tuberosity=, and internal to this is a =groove= for the palatine vein. In the middle line is the =median palatine suture= (Sutura palatina mediana). In the line of the suture, a little behind the central incisors, is the =foramen incisivum=, through which the palato-labial artery passes. On either side, parallel with the alveolar part of the maxilla, is the =palatine groove= (Sulcus palatinus), which contains the palatine vessels and nerve. It is continuous at the anterior palatine foramen with the palatine canal, which is situated between the maxilla and the palate bone. The =palatine cleft= (Fissura palatina) is the narrow interval along the outer margin of the palatine process of the premaxilla; it is closed in the fresh state by cartilage. Scattered along each side of the palate are several vascular foramina. The =transverse palatine suture= (Sutura palatina transversa) is about half an inch from the posterior border. The latter is in a plane through the last molar teeth, and is concave and free.

[Illustration:

FIG. 34.—CRANIAL CAVITY OF HORSE AS SEEN ON SAGITTAL SECTION OF SKULL.

_O_, Frontal sinus; _r_, sphenoidal sinus; _t_, cerebral compartment of cranium; 1–3, ridges (juga) corresponding to fissures of lateral surface of cerebrum; 4, groove for middle cerebral artery; 5, entrance to for. lacerum orbitale; 6, entrance to optic foramen; 7, 8, grooves on sphenoid bone; 9, incisura spinosa; 9′, groove for middle meningeal artery; 10, fossa for pyriform lobe of cerebrum; 11, incisura ovalis; 12, incisura carotica; 13, internal auditory meatus; 14, foramen lacerum basis cranii; 15, hypoglossal foramen; 16, petrous temporal; 17, orifice of aquæductus vestibuli; 18, orifice of aquæductus cochleæ; 19, foramen magnum; 20, petrosal crest; 21, two plates of frontal bone; 22, supraoccipital; 23, basioccipital; 24, tentorium osseum; 25, body of sphenoid. (After Ellenberger-Baum, Top. Anat. d. Pferdes.)]

The =posterior= or =nuchal surface= (Norma occipitalis) is formed by the occipital bone. It is trapezoidal in outline, wider below than above, concave dorso-ventrally, convex transversely. It is separated from the superior surface by the =occipital crest=, and from the lateral surfaces by the =superior curved lines= (Lineæ nuchæ superiores). Below the crest are two rough areas for the attachment of the complexus muscles. A little lower is a central eminence on the sides of which the ligamentum nuchæ is attached. At the lowest part centrally is the =foramen magnum=, at which the brain and spinal cord meet; this is bounded laterally by the =occipital condyles=, which are flanked by the =paramastoid= or =styloid processes= (Processus jugulares).

The =apex= of the skull is formed by the bodies of the premaxillæ and mandible, carrying the incisor teeth.

THE CRANIAL CAVITY

This cavity incloses the brain, with its membranes and vessels. It is relatively small and is ovoid in shape.

The =superior wall= or =roof= (Calvaria) is formed by the supraoccipital, interparietal, parietal, and frontal bones. In the middle line is the internal sagittal crest, which joins the crista galli in front, and furnishes attachment to the falx cerebri. Posteriorly the crest is continued by the sharp anterior margin of the =tentorium osseum=, which projects downward and forward into the cavity, and gives attachment to the tentorium cerebelli by its sharp lateral edges. Behind this the roof is grooved centrally for the middle lobe or vermis of the cerebellum. Transverse grooves pass from the base of the tentorium osseum to the parieto-temporal canals. The anterior part of the roof is hollowed by the frontal sinus. The occipital part is very thick and strong.

The =lateral walls= are formed by the occipital, parietal, temporal, and frontal bones, and in part by the orbital wings of the sphenoid. Each is crossed obliquely by the =petrosal crest=, which concurs with the projecting margin of the parietal bone and the tentorium osseum in dividing the cavity into cerebral and cerebellar compartments. Behind the crest is a depression for the lateral lobe (hemisphere) of the cerebellum. Below this are the internal auditory meatus and the openings of the aquæductus vestibuli and aquæductus cochleæ.

[Illustration:]

FIG. 35.—FLOOR OF CRANIAL CAVITY OF HORSE.

The roots of the cranial nerves are shown on the left side and are designated by number. _I_, Anterior cranial fossa; _II_, middle cranial fossa; _III_, posterior cranial fossa; _a_, ethmoidal fossa; _b_, ethmoidal foramen; _c_, foramen for nasal branch of ophthalmic artery; _d_, orbital wing of sphenoid bone; _e_, optic fossa; _f_, sella turcica; _g_, spheno-occipital crest; _h_, _h′_, dotted line indicating contour of pituitary body; _h″_, slight elevation representing dorsum sellæ; _i_, _k_, grooves for nerves and cavernous sinus; _l_, depression for pyriform lobe of cerebrum; _m_, groove for middle meningeal artery; _n_, depression for pons; _o_, foramen lacerum anterius; _p_, foramen lacerum posterius; _q_, incisura carotica; _q′_, incisura ovalis; _q″_, incisura spinosa; _r_, depression for medulla oblongata; _s_, hypoglossal foramen; _t_, internal auditory meatus; _u_, foramen magnum; _v_, frontal sinus; _w_, zygomatic process of temporal bone; _x_, section of petrous temporal; _y_, section of occipital bone; _z_, crista galli; 1, 1′, 1″, dotted lines indicating position of olfactory tracts and peduncle. (After Ellenberger-Baum, Top. Anat. d. Pferdes.)]

The roof and lateral walls are marked by digital impressions and vascular grooves.

The =inferior wall= or =floor= (Basis cranii interna) may be regarded as forming three fossæ. The =anterior fossa= (Fossa cranii anterior) supports the frontal and olfactory parts of the cerebrum. It is formed chiefly by the presphenoid, and lies at a higher level than the middle fossa. In front the fossa is divided medially by the =crista galli=, lateral to which are the deep =ethmoidal= or =olfactory fossæ= for the olfactory lobes. The =ethmoidal= or =internal orbital foramen= perforates the cranial wall at the outer side of these fossæ. Further back the central part of the surface is slightly elevated, and is flanked by shallow depressions which support the olfactory peduncles. Posteriorly is a bony shelf which covers the entrance to the =optic foramina=; the edge of this shelf and the posterior borders of the orbital wings of the sphenoid may be taken as the line of demarcation between the anterior and middle fossæ. The =middle fossa= (Fossa cranii media) is the widest part of the cavity. It extends backward to the internal spheno-occipital and petrosal crests, thus corresponding to the postsphenoid. In its middle is a small fossa, the sella turcica, in which the pituitary body, or hypophysis cerebri, is situated. On either side are two grooves for nerves; the inner one transmits the ophthalmic, third, and sixth nerves to the foramen lacerum orbitale; the outer one leads to the foramen rotundum, and lodges the maxillary nerve. External to the grooves is a depression for the pyriform lobe of the cerebrum. The =posterior fossa= (Fossa cranii posterior) corresponds to the basilar part of the occipital bone. It contains the medulla, pons, and cerebellum. In front is a median depression (Fossa pontis) for the pons. The surface behind this is concave transversely and slopes gently downward to the foramen magnum; it supports the medulla. On either side are the =foramen lacerum basis cranii= and the =hypoglossal foramen=.

The =anterior= or =nasal wall= is formed by the cribriform plate of the ethmoid, which separates the cranium from the nasal cavity. It is perforated by numerous foramina for the passage of the olfactory nerve-bundles.

[Illustration:]

FIG. 36.—MEDIAN SECTION OF SKULL OF HORSE WITHOUT THE MANDIBLE.

The septum nasi is removed, but the mucous membrane on the turbinal bones is retained. _a_, _a′_, Superior turbinal bone, dotted line indicating limit between anterior coiled part and posterior uncoiled part; _b_, _b′_, superior turbinal folds, inclosing bars of cartilage; _c_, fold of mucous membrane formed by union of _b_ and _b′_; _d_, _d′_, anterior coiled and posterior uncoiled part of inferior turbinal, dotted line indicating septum between them; _e_, _f_, inferior turbinal folds, former (alar fold) inclosing bar of cartilage; _g_, _h_, _i_, superior, middle, inferior meatus; _o_, _o′_, frontal sinus; partial septum between _o_ and _o′_; _q_, nasal part of frontal sinus (nasal sinus); _r_, lateral mass of ethmoid bone; _s_, sphenoidal sinus; _t_, cranial cavity; _u_, opening made in superior turbinal bone at point where drainage of frontal sinus may be obtained. (After Ellenberger, in Leisering's Atlas.)]

THE NASAL CAVITY

The =nasal cavity= (Cavum nasi) is a longitudinal passage which extends through the upper part of the face. It is divided into right and left halves by a median =septum nasi=. The =lateral walls= are formed by the maxilla, premaxilla, and the perpendicular part of the palate bones. Attached to them are the turbinal bones, which subdivide each nasal fossa into three =meatuses= (Meatus nasi). This wall is crossed obliquely by the =canal= and =groove= for the =naso-lacrimal duct=, and its posterior part is perforated by the =sphenopalatine foramen=. The =superior wall= or =roof= is formed by the frontal and nasal bones. It is concave from side to side,

and nearly straight longitudinally, except in the posterior part, where it curves downward. It presents a median elevation, the =nasal crest=. The =inferior wall= or =floor= is formed by the palatine processes of the premaxillæ and maxillæ, and the horizontal parts of the palate bones. It is wider but considerably shorter than the roof. It is concave transversely, and nearly horizontal from before backward, except in the posterior third, where there is a slight declivity. The anterior part presents a median groove for the cartilaginous septum, and a furrow for the organ of Jacobson on either side. On either side of the palatine processes of the premaxillæ is the =palatine cleft=.

The =septum nasi= is incomplete in the macerated skull. It is formed by the perpendicular plate of the ethmoid behind, and the vomer below. In the fresh state it is completed by a plate of cartilage.

The =superior meatus= (Meatus nasi superior) is a narrow passage between the roof and the superior turbinal bone. It ends at the cribriform plate of the ethmoid. The =middle meatus= (Meatus nasi medius) is the space between the two turbinal bones. In its posterior part is the very narrow opening into the maxillary sinus. The =inferior meatus= (Meatus nasi inferior) is the channel along the floor which is overhung by the inferior turbinal bone. It is much the largest and is the direct path between the anterior and posterior nares.

The external aperture is bounded by the nasal bones and the premaxillæ.

[Illustration:

FIG. 37.—CROSS-SECTION OF NASAL REGION OF SKULL OF HORSE; THE SECTION PASSES THROUGH THE ANTERIOR END OF THE FACIAL CREST, AND BETWEEN THE THIRD AND FOURTH CHEEK TEETH.

(After Ellenberger, in Leisering's Atlas.)]

[Illustration:

FIG. 38.—CROSS-SECTION OF NASAL REGION OF SKULL OF HORSE; THE SECTION IS CUT ABOUT HALFWAY BETWEEN THE ORBIT AND THE ANTERIOR END OF THE FACIAL CREST, AND PASSES BETWEEN THE FIFTH AND SIXTH CHEEK TEETH.

_a_, Superior, _b_, inferior turbinal bone; _c_, _d_, cavities of _a_ and _b_; _e_, common meatus; _f_, superior, _g_, middle, _h_, inferior meatus; _i_, placed over ridge in maxillary sinus; _k_, communication between outer and inner (turbinal) part of maxillary sinus; _l_, naso-maxillary opening; _m_, naso-lacrimal canal; _n_, infraorbital canal. (After Ellenberger, in Leisering's Atlas.)]

The posterior extremity or fundus is separated from the cranial cavity by the cribriform plate of the ethmoid, and is largely occupied by the lateral masses of that bone.

THE PARANASAL SINUSES

Connected directly or indirectly with the nasal cavity, of which they are diverticula, are four pairs of air-sinuses (Sinus paranasales), viz., maxillary, frontal, sphenopalatine, and ethmoidal.

The =maxillary sinus= (Sinus maxillaris) is the largest. Its external wall is formed by the maxilla, the lacrimal, and the malar. It is bounded internally by the maxilla, the inferior turbinal, and the lateral mass of the ethmoid bone. It extends backward to a transverse plane in front of the root of the supraorbital process, and its anterior limit is indicated approximately by a line drawn from the anterior end of the facial crest to the infraorbital foramen. Its upper boundary corresponds to a line drawn backward from the supraorbital foramen parallel to the facial crest. The floor is formed by the alveolar part of the maxilla; it is very irregular and is crossed by bony plates running in various directions. The last three cheek teeth project up into the cavity to an extent which varies with age; they are covered by a thin plate of bone. The cavity is divided into anterior and posterior parts by an oblique =septum=. The outer margin of the septum is commonly about one and a half to two inches (ca. 3.5 to 5 cm.) from the anterior end of the facial crest; from here it is directed inward, backward, and upward. The upper part of the septum (formed by the posterior end of the inferior turbinal bone) is very delicate and usually cribriform.

The position of the septum is quite variable. It is not rare to find it further forward, and in some cases it is further back than is stated above. In the recent state, _i. e._, when covered by the mucous membrane on both surfaces, it is nearly always complete, but in very exceptional cases there is an opening of variable size in the upper part.

The =anterior compartment=, often called the =inferior maxillary sinus=, is partially divided by the infraorbital canal into an external maxillary part and an internal smaller turbinal part. The latter communicates with the middle meatus by a very narrow slit situated at its highest part. The =posterior compartment=, often called the =superior maxillary sinus=, is also crossed by the infraorbital canal, internal to which it opens freely into the sphenopalatine sinus. It communicates dorsally with the frontal sinus through the large oval =fronto-maxillary opening=, situated at the level of the osseous lacrimal canal and the corresponding part of the inner wall of the orbit; the orifice is commonly about one and a half to two inches (ca. 4 to 5 cm.) long and an inch or more (2 to 3 cm.) wide. Just in front of this, and covered by a thin plate, is the narrow =naso-maxillary fissure= (Aditus naso-maxillaris), by which the sinus opens into the posterior part of the middle meatus.

The foregoing statements refer to the arrangement in the average adult animal. In the foal the cavity (with the exception of its turbinal part) is largely occupied by the developing teeth. In horses five to six years of age the maxillary part of the sinus is still filled up to a large degree by the embedded parts of the teeth. As the teeth are extruded to compensate the wear, more and more of the cavity becomes free, until in old age only the short roots project up in the floor, covered by a layer of bone. Other facts in this connection will be given in the description of the teeth. In exceptional cases the posterior part of the inferior turbinal is smaller than usual and leaves a considerable interval, through which the maxillary sinus communicates with the nasal cavity.

[Illustration:

FIG. 39.—SKULL OF HORSE, LATERAL VIEW WITHOUT MANDIBLE. THE SINUSES ARE OPENED UP.

_a_, Posterior part, _b_ and _c_, anterior part of frontal sinus; _d_, roof of superior meatus; _e_, lateral mass of ethmoid bone; _f_, _f′_, naso-lacrimal duct, exposed in its posterior part; _g_, _h_, posterior and anterior compartments of maxillary sinus (also designated as superior and inferior maxillary sinuses); _i_, septum between _g_ and _h_; _k_, lower limit of upper thin and partly membranous portion of septum; _l_, infraorbital canal; _m_, turbinal part of maxillary sinus; _n_, bullous prominence of inferior turbinal; _o_, orbit; _p_, infraorbital foramen; _q_, continuation of infraorbital canal to premaxilla; _r_, limit of maxillary sinus. (After Ellenberger, in Leisering's Atlas.)]

The =frontal sinus= (Sinus concho-frontalis) consists of frontal and turbinal parts. The frontal part is bounded chiefly by the two plates of the frontal bone, but its floor is formed in part by the lateral mass of the ethmoid. It extends forward to a plane through the anterior margins of the orbits, backward to one through the temporal condyles, and outward into the root of the supraorbital process. It is separated from the sinus of the opposite side by a complete =septum=. It is partially subdivided by a number of bony plates. The turbinal part is situated in the posterior part of the superior turbinal bone, roofed in by the nasal and lacrimal bones. It extends forward to a transverse plane about half-way between the anterior margin of the orbit and the end of the facial crest. Behind it is in free communication with the frontal part over the lateral mass of the ethmoid. It is separated from the nasal cavity by the thin turbinal plate. The frontal and maxillary sinuses communicate through the large opening described above.

The =sphenopalatine sinus= (Sinus sphenopalatinus) consists of two parts which communicate under the lateral mass of the ethmoid. The sphenoidal (posterior) part is excavated in the body of the presphenoid. The palatine (anterior) part is between the two plates of the perpendicular part of the palate bone, under the lateral mass of the ethmoid; it communicates freely with the maxillary sinus. The septum between the right and left sinuses is not usually median in the sphenoidal part.

In about one-third of the cases (according to Paulli) the sphenoidal and palatine parts are separated by a transverse septum, and the sphenoidal part then communicates only with the lower ethmoidal meatuses.

The term =ethmoidal sinus= is often applied to the cavity of the largest ethmoturbinal. It communicates with the maxillary sinus.

[Illustration:

FIG. 40.—SKULL OF HORSE, DORSAL VIEW, WITH SINUSES EXPOSED BY REMOVAL OF THE OUTER PLATE OF BONE.

_1_, Frontal bone; _2_, nasal bone; _3_, lacrimal bone; _4_, maxilla; _a_, posterior part of frontal sinus; _a′_, middle part of frontal sinus; _b_, anterior (turbinal) part of frontal sinus; _c_, lateral mass of ethmoid bone; _d_, roof of superior meatus; _e_,

fronto-maxillary opening; _f_, naso-maxillary opening below plate which forms the anterior margin of _e_; _g_, _h_, posterior and anterior compartments of maxillary sinus—often called the superior and inferior maxillary sinuses; _i_, septum between _g_ and _h_; _k_, orbit; _l_, point at which superior turbinal bone may be perforated to obtain drainage into nasal cavity. (After Ellenberger, in Leisering's Atlas.)]

THE BONES OF THE THORACIC LIMB THE SCAPULA

The =scapula= is a flat bone, situated on the anterior part of the lateral wall of the thorax, and extending obliquely from the vertebral end of the seventh or eighth rib to the sternal end of the first rib. It is curved slightly and slopes outward in adaptation to the form of the thoracic wall. It is triangular in outline, and has two surfaces, three borders, and three angles.

The =external surface= or =dorsum= (Facies lateralis s. dorsalis) is divided into two fossæ by the =spine= (Spina scapulæ), which extends from the vertebral border to the neck of the bone, where it gradually subsides. The free edge of the spine is thick, rough, and in great part subcutaneous. A little above its middle is a variable prominence, the =tubercle= of the spine (Tuber spinæ), to which the trapezius muscle is attached. The =supraspinous fossa= (Fossa supraspinata) is situated in front of the spine, and the =infraspinous fossa= (Fossa infraspinata) behind it. The former is much the smaller of the two; it is smooth and is occupied by the supraspinatus muscle. The infraspinous fossa lodges the infraspinatus muscle; it is wide and smooth in its upper part, narrower below, where it is marked by several rough lines for the attachment of the teres minor muscle; near the neck is the nutrient foramen, and a little lower is a vascular groove.

[Illustration:

FIG. 41.—LEFT SCAPULA OF HORSE, EXTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =costal surface= or =venter= (Facies costalis) is hollowed in its length by the =subscapular fossa= (Fossa subscapularis); this occupies nearly the whole of the lower part of the surface, but is pointed above and separates two rough triangular areas (Facies serrata), to which the serratus magnus is attached. In the lower third there is a vascular furrow with several branches.

The =anterior= or =cervical border= (Margo cranialis) is convex and rough above, concave and smooth below.

The =posterior= or =dorsal border= (Margo caudalis) is slightly concave. It is thick and rough in its upper third, thin in its middle, and thickens again below.

The =superior= or =vertebral border= (Margo dorsalis s. basis) carries the =scapular cartilage= (Cartilago scapulæ). In the young subject the edge of the bone is thick, and is pitted by impressions into which the cartilage fits. The cartilage is the unossified part of the fœtal scapula. Its lower edge fits the depressions and elevations of the bone. It thins out toward the free edge, which is convex and lies alongside of the upper parts of the vertebral spines. In front it continues the line of the scapula, but behind it forms a rounded projection. The lower part of the cartilage undergoes more or less ossification, so that the vertebral border of the bone in old subjects is thin, irregular, and porous.

[Illustration:

FIG. 42.—LEFT SCAPULA OF HORSE, COSTAL SURFACE.—(After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =anterior= or =cervical angle= (Angulus cranialis) is at the junction of the anterior and vertebral borders and lies opposite to the second thoracic spine. It is relatively thin and is about a right angle.

The =posterior= or =dorsal angle= (Angulus caudalis) is thick and rough; its position can be determined readily in the living animal.

The =inferior= or =articular angle= (Angulus glenoidalis) is joined to the body of the bone by the =neck= of the scapula (Collum scapulæ). It is enlarged, especially in the sagittal direction. It bears the =glenoid cavity= (Cavitas glenoidalis) for articulation with the head of the humerus. The cavity is oval in outline, and its margin is cut into in front by the =glenoid notch= (Incisura glenoidalis), and is rounded off externally; just above its postero-external part is a tubercle to which a tendon of the teres minor is attached. The =bicipital tuberosity= or =tuber scapulæ= is the large rough prominence in front, to which the tendon of origin of the biceps brachii is attached; projecting from its inner side is the small =coracoid process= (Processus coracoideus), from which the coraco-brachialis muscle arises.

=Development.=—The scapula has four centers of ossification, viz., one each for the body of the bone, the bicipital and coracoid processes, the anterior part of the glenoid cavity, and the tuber spinæ. The last ossifies after birth and fuses with the spine about the third year. The bicipital tuberosity and coracoid fuse with the body of the bone about the end of the first year.

In old subjects the spongy substance disappears at the middle part of the fossæ, so that the bone consists here of a thin layer of compact substance. Considerable ossification of the cartilage is usual, the borders become much rougher, the muscular lines are more pronounced, and a medullary cavity may appear in the neck. Much variation occurs in dimensions and slope. The average ratio between the length and breadth (scapular index) is about 1 ■ 0.5, but in many cases the base is relatively wider. The inclination on a horizontal plane varies from 50 to 65 degrees. Exceptionally the coracoid process reaches a length of an inch or more (2½ to 3 cm.), and the chief nutrient foramen may be on the posterior border or in the subscapular fossa.

[Illustration:

FIG. 43.—DISTAL END OF LEFT SCAPULA OF HORSE, END VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE HUMERUS

The =humerus= is a long bone which extends from the shoulder above, where it articulates with the scapula, to the elbow below and behind, where it articulates with the radius and ulna. It is directed obliquely downward and backward, forming an angle of about 55 degrees with a horizontal plane. It may be divided into a shaft and two extremities.

[Illustration:

FIG. 44.—PROXIMAL END OF LEFT HUMERUS OF HORSE, END VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =shaft= or =body= (Corpus humeri) is irregularly cylindrical and has a twisted appearance. It may be regarded as having four surfaces. The =external surface= is smooth and is spirally curved, forming the =musculo-spiral groove= (Sulcus musculi brachialis), which contains the brachialis muscle; the groove is continuous with the posterior surface above and winds around toward the front below. The =internal surface= is nearly straight in its length, rounded from side to side, and blends with the anterior and posterior surfaces. Just above its middle is the =internal= or =teres tubercle= (Tuberositas teres), to which the tendon of the latissimus dorsi and teres major muscles is attached. The =nutrient foramen= is in the lower third of this surface. The =anterior surface= is triangular, wide and smooth above, narrow and roughened below. It is separated from the external surface by a distinct border, which bears on its upper part the =deltoid tuberosity= (Tuberositas deltoidea). From the latter a rough line curves upward and backward to the outer surface of the neck, and gives origin to the external head of the triceps muscle. Below the tuberosity the border inclines forward, becomes less salient, and ends at the coronoid fossa. The =posterior surface= is rounded from side to side and smooth.

[Illustration:

FIG. 45.—LEFT HUMERUS OF HORSE, INTERNAL SURFACE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 46.—LEFT HUMERUS OF HORSE, EXTERNAL SURFACE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =proximal extremity= consists of the head, neck, two tuberosities, and the bicipital groove. The =head= (Caput humeri) presents an almost circular convex articular surface, which is about twice as extensive as the glenoid cavity of the scapula, with which it articulates. In front of the head is a fossa, in which are several foramina. The neck (Collum humeri) is well defined behind, but is practically absent elsewhere. The =external tuberosity= (Tuberculum majus) is placed antero-externally, and consists of two parts; the anterior part forms the outer boundary of the bicipital groove and gives attachment to the external branch of the supraspinatus muscle; the posterior part gives attachment to the short insertion of the infraspinatus, while its outer surface is coated with cartilage, over which the chief tendon of the same muscle passes to be inserted into a triangular facet on the outer aspect of the anterior part. The =internal tuberosity= (Tuberculum minus) is less salient, and consists of anterior and posterior parts; the anterior part forms the inner boundary of the bicipital groove, and furnishes insertion to the inner branch of the supraspinatus above, and the posterior deep pectoral muscle below; the posterior part gives attachment to the subscapularis muscle. The =bicipital= or =intertubercular groove= (Sulcus intertubercularis) is situated in front; it is bounded by the anterior parts of the tuberosities, and is subdivided by an intermediate ridge. The groove is covered in the fresh state by cartilage, and lodges the

tendon of origin of the biceps brachii muscle. Just below the intermediate ridge is a small fossa in which several foramina open.

[Illustration:

FIG. 47.—LEFT HUMERUS OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =distal extremity= has an oblique surface for articulation with the radius and ulna, which consists of two condyles of very unequal size, separated by a ridge. The =internal condyle= (Condylus medialis) is much the larger, and is crossed by a sagittal groove, on the anterior part of which there is usually a synovial fossa. Posteriorly the groove extends upward considerably above the rest of the articular surface and reaches the olecranon fossa, and this part articulates with the semilunar notch of the ulna. The =external condyle= (Condylus lateralis) is much smaller and is placed somewhat lower and further back, giving the extremity an oblique appearance; it is marked by a wide shallow groove. The =coronoid fossa= (Fossa coronoidea) is situated in front above the groove on the internal condyle; it furnishes origin to part of the extensor carpi, and external to it is a rough depression from which the anterior or common extensor of the digit arises. Behind and above the condyles are two thick ridges, the epicondyles. The =internal= or =flexor epicondyle= (Epicondylus medialis s. flexorius) is the more salient; it furnishes origin to flexor muscles of the carpus and digit, and presents internally a tubercle for the attachment of the internal lateral ligament of the elbow joint. The =external= or =extensor epicondyle= (Epicondylus lateralis s. extensorius) bears externally the =external supracondyloid crest= (Crista condyloidea lateralis), which forms here the outer boundary of the musculo-spiral groove, and gives origin to the extensor carpi. Below this is a rough excavation in which the external lateral ligament is attached. The lower border of the epicondyle gives attachment to the flexor carpi externus. Between the epicondyles is the deep =olecranon fossa= (Fossa olecrani).

=Development.=—The humerus ossifies from six centers, viz., three primary centers for the shaft and epiphyses, and three secondary centers for the external tuberosity, the deltoid tuberosity, and the internal condyle. The proximal end fuses with the shaft at about three and one-half years, the distal at about one and a half years of age.

THE RADIUS

The =radius= is much the larger of the two bones of the forearm in the horse. It extends in a vertical direction from the elbow, where it articulates with the humerus, to the carpus below. It is gently curved, the convexity being anterior. It consists of a shaft and two extremities.

The =shaft= (Corpus radii) is curved in its length, somewhat flattened from before backward, and expanded at its ends. It presents for description two surfaces and two borders. The =anterior surface= (Facies dorsalis) is smooth, slightly convex in its length, and rounded from side to side. The =posterior surface= (Facies volaris) is correspondingly concave in its length and is flattened in the transverse direction. At its upper part there is a smooth shallow groove, which concurs with the ulna in the formation of the =interosseous space= of the forearm; the nutrient foramen is in the lower part of this groove. Below this there is in the young subject a narrow, rough, triangular area to which the ulna is attached by an interosseous ligament; in the adult the two bones are fused here. A variable rough elevation below the middle of the surface and close to the internal border gives attachment to the superior check ligament. The =internal border= (Margo medialis) is slightly concave in its length and is largely subcutaneous; at its proximal end there is a smooth area on which the tendon of insertion of the brachialis muscle lies, and a small rough area just below gives attachment to that muscle and the long internal lateral ligament of the elbow joint. The =external border= (Margo lateralis) is more strongly curved, but presents no special features.

The =proximal extremity= or =head= (Capitulum radii) is flattened from before backward and wide transversely. It presents an articular surface (Fovea capituli) which corresponds to that on the distal end of the humerus; it is crossed by a central sagittal ridge, which has a synovial fossa on its posterior part, and ends in front at a prominent lip, the =coronoid process= (Processus coronoideus). Just below the posterior border there are two concave facets for articulation with the ulna, and between these and the interosseous space is a quadrilateral rough area at which the two bones are united by an interosseous ligament. At the inner side of the anterior surface is the =bicipital tuberosity= (Tuberositas radii), into which the biceps tendon is inserted. The =internal tuberosity= is continuous with the preceding eminence, and furnishes attachment to the short part of the internal lateral ligament. The =external tuberosity= is more salient; it gives attachment to the external lateral ligament and to the anterior and lateral extensor muscles of the digit.

[Illustration:

FIG. 48.—LEFT RADIUS AND ULNA OF HORSE, EXTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 49.—LEFT RADIUS AND ULNA OF HORSE, POSTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =distal extremity= is also compressed from before backward. It presents the =carpal articular surface= (Facies articularis carpea) which consists of three parts. The inner facet is the largest, is quadrilateral, concavo-convex from before backward, and articulates with the radial carpal bone (or scaphoid); the middle one is somewhat similar in form but smaller, and articulates with the intermediate carpal bone (or semilunar); the outer facet is smaller, is convex, and articulates below with the ulnar carpal (or cuneiform) and behind with the accessory carpal (or pisiform). The anterior surface presents three =grooves=, separated by ridges. The middle one is vertical and gives passage to the tendon of the extensor carpi radialis; the outer one is similar and contains the tendon of the anterior extensor of the digit; the inner one is small and oblique and lodges the tendon of the extensor carpi obliquus. The posterior aspect is crossed by a rough ridge, below which are three depressions. On either side is a tuberosity (Tuberculum ligamenti) to which the lateral ligament is attached. The outer one is marked by a small vertical groove for the passage of the lateral extensor tendon.

=Development.=—The radius ossifies from four centers, viz., one each for the shaft, the two extremities, and the outer part of the distal end; the last is morphologically the distal end of the ulna which has fused with the radius, and the line of fusion is often indicated by a distinct groove on the carpal articular surface. The proximal extremity unites with the shaft at about one and a half years, the distal end at about three and a half years.

[Illustration:

FIG. 50.—UPPER HALF OF RADIUS AND ULNA OF HORSE, INTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE ULNA

The =ulna= of the horse is a reduced long bone situated behind the radius, with which it is partially fused in the adult.

The =shaft= (Corpus ulnæ) is three-sided and tapers to a point below. The =anterior surface= (Facies dorsalis) is applied to the posterior surface of the radius, and below the interosseous space the two bones are fused in the adult. The surface which enters into the formation of the space is smooth and usually presents a small nutrient foramen, directed upward. Above the space it is rough and is attached to the radius by an interosseous ligament which is usually permanent. The =internal surface= (Facies medialis) is smooth and slightly concave. The =external surface= (Facies lateralis) is flattened. The =internal= and =external borders= are thin and sharp, except at the interosseous space. The =posterior border= is slightly concave in its length and is rounded. The lower end is pointed and is usually a little below the middle of the radius. It is commonly continued by a fibrous cord to the distal external tuberosity of the radius, but this band may be replaced in part or entirely by bone.

The =proximal extremity= is the major part of the bone. It projects upward and somewhat backward behind the lower end of the humerus, and forms a lever arm for the extensor muscles of the elbow. The =internal surface= is concave and smooth. The =external surface= is convex and is roughened above. The =anterior border= bears on its middle a pointed projection, the =processus anconæus= or “beak,” which overhangs the =semilunar notch= or =sigmoid cavity= (Incisura semilunaris). The latter is triangular in outline, concave from above downward, and articulates with the humerus; in the middle of its lower part is an extensive synovial fossa. Just below the notch are two convex =facets= which articulate with those on the posterior aspect of the proximal end of the radius. The =posterior border= is nearly straight, and is thick and rounded. The free end or summit is a rough tuberosity, the =olecranon=, which gives attachment to the triceps brachii and other muscles.

The primitive =distal extremity= has, as previously stated, fused with the radius.

=Development.=—The ulna ossifies from three centers, of which one is for the main part of the bone, one for the olecranon, and one for the distal end. The cartilaginous embryonic ulna extends the entire length of the forearm. The lower part of the shaft is usually reduced to a small fibrous band or may disappear entirely; in some cases a variable remnant of it ossifies. The distal extremity fuses early with the radius. The olecranon unites with the rest of the bone at three to three and a half years. A medullary canal appears to occur constantly in the adult—contrary to the statements of some authors.

THE CARPUS

The =carpus= of the horse consists of seven or eight bones (Ossa carpi) arranged in two rows, proximal or antibrachial, and distal or metacarpal. The (abbreviated) names and relative positions of the bones of the left carpus as seen from in front are indicated below.

Proximal Row: Radial Intermediate Ulnar Accessory

Distal Row: First Second Third Fourth

THE RADIAL CARPAL BONE

The =radial carpal= bone (Os carpi radiale, scaphoid) is the largest bone of the upper row; it is somewhat compressed laterally, and is clearly six-sided. The =superior= or =proximal surface= is convex in front, concave behind, and articulates with the inner facet on the distal end of the radius. The =inferior= or =distal surface= is also convex in front and concave behind; it articulates with the second and third carpal bones. The =external surface= bears upper and lower facets on its anterior part for articulation with the intermediate; between and behind these it is excavated and rough. The =anterior= or =dorsal surface= is rough and slightly convex. The =internal surface= and the =posterior= or =volar surface= are rough and tuberculate.

[Illustration:

FIG. 51.—SAGITTAL SECTION OF UPPER PART OF RADIUS AND ULNA OF HORSE. _Cm_, Medullary cavity of ulna.]

THE INTERMEDIATE CARPAL BONE

The =intermediate carpal= bone (Os carpi intermedium, semilunar, lunar) is somewhat wedge-shaped, wider in front than behind. The =superior= or =proximal surface= is saddle-shaped, and articulates with the middle facet on the distal end of the radius. The =inferior= or =distal surface= is smaller, convex in front, concave behind, and articulates with the third and fourth carpal bones. The =internal surface= has upper and lower facets for articulation with the radial carpal, and between these it is excavated and rough. The =external surface= is similar to the preceding and articulates with the ulnar carpal. The =anterior= or =dorsal surface= is rough and slightly convex. The =posterior= or =volar surface= bears a tuberosity on its lower part.

THE ULNAR CARPAL BONE

The =ulnar carpal= bone (Os carpi ulnare, cuneiform) is the smallest and most irregular bone of the upper row. The =superior= or =proximal surface= is concave, and fits the lower part of the outer facet on the distal end of the radius. The =inferior= or =distal surface= is oblique and undulating for articulation with the fourth carpal bone. The =internal surface= has upper and lower facets for articulation with the intermediate. The =anterior= or =dorsal= and =external surfaces= are continuous, convex, and rough. The =posterior= or =volar surface= is oblique, and bears a concave facet for articulation with the accessory carpal bone; below this is a tubercle.

[Illustration:

FIG. 53.—LEFT CARPAL BONES OF HORSE, WITH ADJACENT ENDS OF RADIUS AND METACARPUS; EXTERNAL VIEW.

_Ca_, Accessory carpal bone; _Cr_, radial carpal; _Ci_, intermediate carpal; _Cu_, ulnar carpal; _C1–4_, first to fourth carpals; _Mc. II_, _III_, _IV_, metacarpal bones; _1_, groove for tendon of extensor carpi obliquus; _2_, groove for lateral extensor tendon; _3_, groove for tendon of flexor carpi externus; _4_, metacarpal tuberosity. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE ACCESSORY CARPAL BONE

The =accessory carpal= bone (Os carpi accessorium, pisiform) is situated behind the ulnar carpal bone and the outer part of the distal end of the ulna. It is discoid and presents for description two surfaces and a circumference. The =internal surface= is concave and forms the outer wall of the carpal groove. The =external surface= is convex and rough; a smooth groove for the outer tendon of the flexor carpi externus crosses its anterior part obliquely downward and slightly forward. The =anterior border= bears two facets;

the upper one is concave and articulates with the back of the outer facet on the distal end of the radius; the lower one is convex and articulates with the ulnar carpal bone. The remainder of the circumference is rounded and rough.

The accessory does not directly bear weight, and may be regarded as a sesamoid bone interposed in the course of the tendons of the middle and external flexors of the carpus, which it enables to act at a mechanical advantage. The posterior border furnishes attachment to the transverse carpal ligament, which completes the carpal canal for the flexors of the digit.

THE FIRST CARPAL BONE

The =first carpal= bone (Os carpale primum, trapezium) is a small inconstant bone, commonly about the size and shape of a pea, which is situated in the lower part of the internal lateral ligament behind the second carpal bone.

This bone appears to be absent on both sides in about half of the cases; in a good many subjects it is present on one side only. In size it varies from a minute nodule to a discoid mass 10 to 12 mm. in length. In exceptional cases it articulates with both the second carpal and the second (inner) metacarpal bone, in other cases with the former only, but in the majority of specimens no articular facet is present.

THE SECOND CARPAL BONE

The =second carpal= bone (Os carpale secundum, trapezoid) is the smallest constant bone of the lower row, and is irregularly hemispherical in shape. The =superior= or =proximal surface= is a convex facet which is continued upon the =posterior= or =volar surface= and articulates with the posterior part of the radial carpal. The =external surface= faces obliquely outward and forward, and bears three facets for articulation with the third carpal bone. The =anterior= or =dorsal= and the =internal surface= bear a tuberosity to which the lateral ligament is attached. The =inferior= or =distal surface= is articular and consists of a large flattened facet for the inner (second) metacarpal bone, and a small one for the large (third) metacarpal bone. Some specimens have a small facet on the lower part of the posterior surface which articulates with the first carpal bone.

[Illustration:

FIG. 54.—CARPAL BONES OF HORSE, WITH ADJACENT ENDS OF RADIUS AND METACARPUS; ANTERIOR VIEW. THE ACCESSORY AND FIRST CARPAL BONES ARE NOT SHOWN.]

[Illustration:

FIG. 55.—CARPAL ARTICULAR SURFACE OF RADIUS AND PROXIMAL ARTICULAR SURFACES OF CARPAL AND METACARPAL BONES, LEFT SIDE. THE ACCESSORY AND FIRST CARPAL BONES ARE NOT SHOWN.

_Cr_, Radial carpal; _Ci_, intermediate carpal; _Cu_, ulnar carpal; _C2_, _C3_, _C4_, second, third, and fourth carpals; _Mc.II_, second or inner small metacarpal bone; _Mc.III_, third or large metacarpal bone; _Mc.IV_, fourth or outer small metacarpal bone; _1_, _2_, grooves for tendons of anterior extensor and extensor carpi radialis; _3_, metacarpal tuberosity. Arrows indicate relations of facets. Short arrow points to facet on ulnar carpal for articulation with accessory carpal. (After Schmaltz, Atlas. d. Anat. d. Pferdes.)]

THE THIRD CARPAL BONE

The =third carpal= bone (Os carpale tertium, os magnum) is much the largest bone of the lower row, forming more than two-thirds of the width of the latter. It is flattened from above downward, and is twice as wide in front as behind. The =superior= or =proximal surface= consists of two facets separated by an antero-posterior ridge; the inner facet is concave and articulates with the radial carpal; the outer facet—for the intermediate carpal—is concave in front and convex behind, where it encroaches on the posterior surface. The =inferior= or =distal surface= is slightly undulating, and articulates almost entirely with the large (third) metacarpal bone, but it usually bears a small oblique facet at its inner side for the inner (second) metacarpal, and there is commonly a non-articular depression externally. The _internal surface_ faces backward and inward, and bears three facets for articulation with the second carpal, between which it is excavated and rough. The =external surface= has two facets for articulation with the fourth carpal, and is depressed and rough in its middle. The =anterior= or =dorsal surface= is convex and is crossed by a rough transverse ridge. The =posterior= or =volar surface= is relatively small, and is rounded; its upper part is encroached upon by the superior articular surface, below which it is rough.

THE FOURTH CARPAL BONE

The =fourth carpal= bone (Os carpale quartum, unciform) is somewhat wedge-shaped, and is readily distinguished from the second by its greater size and its posterior tubercle. The =superior= or =proximal surface= articulates with the intermediate and ulnar; it is convex and curves outward, backward, and downward, encroaching on the external and posterior surfaces. The =inferior= or =distal surface= bears two inner facets for the large (third) metacarpal and an outer one for the external (fourth) metacarpal bone. The =internal surface= has two or three facets for articulation with the third carpal, between which it is excavated and rough. The =anterior= or =dorsal surface= is convex and rough. The =external surface= is small, being encroached upon by the superior articular surface. The =posterior= or =volar surface= bears a tubercle on its lower part.[21]

THE CARPUS AS A WHOLE

The bones of the carpus, exclusive of the accessory, form an irregular quadrangular mass, the width of which is about twice the height or the antero-posterior diameter. The =anterior= or =dorsal surface= is convex from side to side, depressed along the line of junction of the two rows, and prominent below. The =posterior= or =volar surface= is in general slightly convex, but very irregular. It forms with the accessory the =carpal groove= (Sulcus carpi), which in the recent state is rendered smooth by the posterior ligament; it is converted into the =carpal canal= (Canalis carpi) for the flexor tendons by the transverse carpal ligament, which stretches across from the accessory bone to the inner side. The =proximal surface= is widest internally and is elevated in front, concave behind; it is entirely articular and adapted to the carpal articular surface of the radius. The =distal surface= is also articular and is irregularly faceted in adaptation to the surfaces of the metacarpal bones; each of the lower bones usually articulates with two metacarpal bones, but sometimes the third does not bear on the inner metacarpal bone. The =lateral surfaces= are both irregular and rough, the internal one being the wider. With the exception of the accessory, ulnar, and second, each bone articulates with two bones of the other row.

=Development.=—Each ossifies from a single center.

THE METACARPUS

Three =metacarpal bones= (Ossa metacarpalia) are present in the horse. Of these, only one, the third or large metacarpal bone, is fully developed and carries a digit; the other two, the second and fourth, are much reduced, and are commonly called the internal and external small metacarpal or “splint” bones.

[Illustration:

FIG. 56.—DISTAL ROW OF CARPAL BONES, METACARPUS, FIRST AND SECOND PHALANGES, AND PROXIMAL SESAMOID BONES OF HORSE; POSTERIOR VIEW, LEFT SIDE.

The fourth (external) metacarpal bone is wrongly numbered as I. (After Schmaltz, Atlas. d. Anat. d. Pferdes.)]

[Illustration:

FIG. 57.—LEFT METACARPAL AND DIGITAL BONES OF HORSE, INTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE LARGE METACARPAL BONE

This (Os metacarpale tertium) is a very strong long bone, placed vertically between the carpus above and the first phalanx below. It consists of a shaft and two extremities.

The =shaft= (Corpus) is semicylindrical, and presents two surfaces and two borders. The =anterior= or =dorsal surface= is smooth, convex from side to side, and nearly straight in its length. The =posterior= or =volar surface= is somewhat convex from side to side and, with the small bones, forms a wide groove which lodges the suspensory ligament. On either side of its upper two-thirds it is roughened for the attachment of the small metacarpal bones. The =nutrient foramen= occurs at the junction of the upper and middle thirds. The lower third is wider and flattened. The borders are rounded.

The =proximal extremity= (Basis) bears an undulating articular surface adapted to the lower row of carpal bones. The greater part supports the third carpal bone; the oblique outer part, separated from the preceding by a ridge, articulates with the fourth, and a

small facet for the second is usually found at the postero-internal angle. On either side is a notch separating two small facets which articulate with the proximal ends of the small metacarpal bones. Toward the inner side of the anterior surface is the =metacarpal tuberosity=, into which the extensor carpi radialis is inserted. The posterior surface is roughened for the attachment of the suspensory ligament.

The =distal extremity= (Trochlea s. Capitulum) presents an articular surface for the first phalanx and the proximal sesamoid bones, which is composed of two condyles, separated by a sagittal ridge; the inner condyle is slightly the larger. On either side is a small fossa, surmounted by a tubercle, for the attachment of the lateral ligaments of the fetlock joint.

The large metacarpal is one of the strongest bones in the skeleton. The compact substance is specially thick in front and internally. The medullary canal extends further toward the ends than in most of the long bones of the horse and there is little spongy bone.

THE SMALL METACARPAL BONES

These are situated on either side of the posterior surface of the large metacarpal bone, and form the sides of the metacarpal groove. Each consists of a shaft and two extremities.

The =shaft= (Corpus) is three-sided and tapers to the distal end. It is variably curved, convex toward the middle line of the limb. The anterior surface is flattened and is rough, except in its lower part; it is attached to the large metacarpal bone by an interosseous ligament, except near the distal end. The abaxial surface is smooth and rounded from side to side above, grooved below. The axial surface is smooth and concave from edge to edge, except below, where it forms a rounded edge.

The =proximal extremity= or =head= (Basis) is relatively large. In the case of the inner bone it usually bears two facets above which support the second and third carpal bones, while the outer bone has here a single facet for articulation with the fourth carpal bone. Each has also two facets for articulation with the large metacarpal, and is elsewhere roughened for the attachment of ligaments and muscles. The inner bone may present a small facet behind for the first carpal bone.

The =distal extremity= (Capitulum) is usually a small nodule, which projects to a variable extent in different subjects, and is easily felt in the living animal. It is situated two-thirds to three-fourths of the way down the region.

The small metacarpal bones vary much in length, thickness, and curvature. In the majority of cases the inner bone is the longer; in other subjects the outer one is the longer or there is no material difference. Sometimes the curvature is very pronounced, so that the distal end causes a decided projection. The distal end is very variable in size and may be a mere point.

=Development.=—The large metacarpal bone ossifies from three centers. The proximal extremity unites with the shaft before birth, the distal extremity toward the middle of the second year. The small metacarpal bones ossify from two centers, one of which is for the proximal extremity. Their distal ends are cartilaginous at birth. Fusion of the middle part of the shaft with the large metacarpal bone is common.

THE PHALANGES

THE FIRST PHALANX

The _first phalanx_ (Phalanx prima)[22] is a long bone, situated between the large metacarpal bone above and the second phalanx below. It is directed obliquely downward and forward, forming an angle of 50 to 55 degrees with the horizontal plane in well-formed limbs. It consists of a shaft and two extremities.

The =shaft= (Corpus) is wider and much thicker above than below, and presents two surfaces and two borders. The =anterior= or =dorsal surface= is convex from side to side and smooth. The =posterior= or =volar surface= is flattened, and bears a triangular rough area, bounded laterally by ridges which begin at the tuberosities above and converge below; this area furnishes attachment to the inferior sesamoidean ligaments. The =borders=, =internal= and =external=, are rounded and have a rough area or a tubercle on their middle parts.

The =proximal extremity= (Basis) is relatively large. It bears an articular surface adapted to the distal end of the large metacarpal bone, consisting of two glenoid cavities separated by a sagittal groove; the inner cavity is a little larger than the outer one. The posterior angles are formed by buttress-like tuberosities for ligamentous attachment. The anterior surface has a slight elevation for

the attachment of the lateral extensor tendon.

The =distal extremity= is smaller, especially in its antero-posterior diameter. It presents a trochlea for articulation with the second phalanx, consisting of a shallow central groove and two lateral convex areas or condyles; the inner area is a little the larger. On either side, just above the margin of the articular surface, is a depression surmounted by a tubercle, to both of which the lateral ligament is attached. Behind the tubercle is a distinct facet to which the superficial flexor tendon is attached.

=Development.= The first phalanx ossifies from three centers. The distal end unites with the shaft before birth, the proximal end early in the first year.

The first phalanx contains a small medullary canal in the middle of the shaft. It may be remarked that the bone is twisted slightly; when placed volar surface down on the table, it touches the latter by three points only, the proximal tuberosities and the internal condyle.

THE SECOND PHALANX

The =second phalanx= (Phalanx secunda)[23] is situated between the first and third phalanges, its direction corresponding to that of the first phalanx. It is flattened from before backward, and its width is greater than its height. It may be described as possessing four surfaces.

The =upper= or =proximal surface= presents two glenoid cavities separated by a low ridge, and articulates with the first phalanx. The middle of the anterior border is elevated and roughened in front for the attachment of the anterior or common extensor tendon. The posterior border is thick and overhanging; in the fresh state its middle part is covered with cartilage, over which the deep flexor tendon passes. On either side there is an eminence, to which the lateral ligament and the superficial flexor tendon are attached.

The =inferior= or =distal surface= is trochlear, and articulates with the third phalanx and third sesamoid bone. It resembles somewhat the trochlea of the first phalanx, but is more extensive and encroaches more on the anterior and posterior surfaces.

The =anterior= or =dorsal surface= is convex from side to side and smooth in its middle; on its lower part are lateral rough depressions, surmounted by tuberosities, to both of which ligaments are attached.

The =posterior= or =volar= surface is smooth, flattened, and slopes obliquely downward and forward. The borders which separate the anterior and posterior surfaces are concave from above downward, rounded from before backward.

=Development.=—The second phalanx ossifies like the first, but the proximal end unites with the shaft two or three months earlier.

[Illustration:

FIG. 58.—PHALANGES AND THIRD SESAMOID OF HORSE, DORSAL ASPECT.]

THE THIRD PHALANX

The =third= or =ungual phalanx= (Phalanx tertia)[24] is entirely inclosed by the hoof, to which it conforms in a general way. It presents for examination three surfaces, three borders, and two angles or wings.

The =articular surface= (Facies articularis) faces upward and backward, and is chiefly adapted to the distal surface of the second phalanx, but a narrow flattened area along the posterior border articulates with the third sesamoid. The =anterior= or =coronary border= forms a central eminence, the =extensor= (or pyramidal) =process= (Processus extensorius), to the front of which the anterior extensor tendon is attached. On either side is a depression for the attachment of the lateral ligament.

The =dorsal= or =wall surface= (Facies dorsalis) slopes downward and forward. The angle of inclination on the ground plane is about 45 to 50 degrees in front. Laterally the height diminishes, and the slope becomes steeper, especially on the inner side. From side to side the curvature is almost semicircular. The surface is rough and porous, resembling pumice stone somewhat. It is perforated by numerous foramina of various sizes; a series of larger ones is situated on or near the lower border. On either side the =dorsal= (or preplantar) =groove= (Sulcus dorsalis) passes forward from the wing and ends at one of the larger foramina. In the fresh state this surface is covered by the matrix of the wall of the hoof. The =inferior= or =distal border= is thin, sharp, and irregularly notched; there is commonly a wider notch in front.

The =volar= or =inferior surface= (Facies volaris) is arched, and divided into two unequal parts by a curved rough line, the =semilunar crest= (Crista semilunaris). The larger anterior area is crescent-shaped, concave, and comparatively smooth; it corresponds to the sole of the hoof, and may be termed the =sole surface=. The posterior part is much smaller, and is semilunar; it is related to the deep flexor tendon, and is hence called the =flexor= or =tendon surface= (Facies flexoria). It presents a central prominent rough area, on either side of which is the =volar= (or plantar) =foramen= (Foramen volare), to which the =volar= (or plantar) =groove= (Sulcus volaris) conducts from the wing. The foramina lead into the =semilunar canal= within the bone, from which small canals lead to some of the foramina of the wall surface. The deep flexor tendon is inserted into the semilunar crest and the central rough area behind it.

The volar grooves and foramina transmit the terminations of the digital arteries into the semilunar canal, where they meet and form a terminal arch, from which branches pass through canals in the bone and emerge through the foramina on the wall surface.

The =angles= or =wings= (Anguli) are prismatic masses which project backward on either side; the inner one is usually the shorter. Each is divided into upper and lower parts by a notch, or is perforated by a foramen which leads to the vascular groove on the side of the wall surface.[25] The upper border carries the lateral cartilage.

The =lateral cartilages= (Cartilagines ungulæ) are rhomboid curved plates, which surmount the wings on either side. They are relatively large and extend above the margin of the hoof sufficiently to be distinctly palpable. The abaxial surface is convex, the axial concave. The upper border is convex and thin; the lower is thicker and is in part attached to the wing. The anterior end is attached by ligament to the side of the second phalanx. The posterior end curves toward its fellow at the heel, and is perforated by numerous foramina for the passage of veins. The central part is mainly hyaline, the periphery mainly fibrous.

It will be noted that the size and form of the wings vary much in different specimens. In the new-born foal the wing is a small, pointed projection. Later the process of ossification invades the lower part of the cartilage to a varying extent. In some cases the greater part of the cartilage is ossified—a condition commonly termed “sidebone.”

=Development.=—The ossification of the terminal phalanx is peculiar. While the proximal articular part is still cartilaginous, a perichondrial cap of bone is formed in relation to the hoof. Later the process extends into the upper part.

=Structure.=—The interior of this bone is channeled by numerous canals for vessels, most of which radiate from the semilunar canal to the wall surface; these are not canals for nutrient vessels of the bone, but transmit arteries to the matrix of the hoof. Thick layers of compact substance are found at the articular and flexor surfaces and the extensor process, _i. e._, at the points of greatest pressure and traction.

THE SESAMOID BONES

The two =proximal= or =great sesamoids= (Ossa sesamoidea phalangis primæ) are situated behind the distal end of the large metacarpal bone, and are closely attached to the first phalanx by strong ligaments. Each has the form of a three-sided pyramid. The =anterior= or =articular surface= conforms to the corresponding part of the distal end of the large metacarpal bone. The =posterior= or =flexor surface= is flattened and oblique; in the fresh state it is covered by a layer of cartilage which also fills the interval between the opposed borders of the two bones, and forms a smooth groove for the deep flexor tendon. The =abaxial surface= is concave, and gives attachment to part of the suspensory ligament; it is separated from the posterior surface by a rough everted border. The =base= faces downward, and furnishes attachment to the inferior sesamoidean ligaments. The =apex= is directed upward and is rounded.

The =third sesamoid= or =navicular= bone (Os sesamoideum phalangis tertiæ) is shuttle-shaped, and is situated behind the junction of the second and third phalanges. Its long axis is transverse, and it possesses two surfaces, two borders, and two extremities. The =articular surface= (Facies articularis) faces upward and forward; it consists of a central eminence, flanked by concave areas, and articulates with the distal end of the second phalanx. The =flexor= or =tendon surface= (Facies flexoria) is directed downward and backward. It resembles the articular surface in form, but is more extensive and not so smooth. In the fresh state it is coated with cartilage and the deep flexor tendon plays over it. The =proximal border= (Margo liber) is wide and grooved in its middle, narrower and rounded on either side. The =distal border= (Margo ligamenti) bears in front a narrow facet for articulation with the third phalanx. Behind this is a groove, which contains a number of relatively large foramina, and is bounded behind by a prominent edge. The =extremities= are blunt-pointed.

[Illustration:]

FIG. 59.—THIRD SESAMOID OR NAVICULAR BONE OF HORSE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

=Development.=—It ossifies from a single center.

THE BONES OF THE PELVIC LIMB

The =pelvic girdle= consists of the ossa coxæ, which unite ventrally at the symphysis pelvis, and articulate with the sacrum dorsally.

OS COXÆ

The =os coxæ= (or os innominatum) forms the skeleton of the hip or haunch, and is the largest of the flat bones. It consists primarily of three parts, the =ilium=, =ischium=, and =pubis=, which meet to form the =acetabulum=, a large cotyloid cavity for articulation with the head of the femur. These parts are fused at about one year of age, but it is convenient to describe them separately.

THE ILIUM

The =ilium= (Os ilium) is the largest of the three parts. It is irregularly triangular and presents two surfaces, three borders, and three angles.

The =gluteal surface= (Facies glutæa) faces upward, backward, and outward. It is wide and concave in front, narrower and convex behind. The wide part is crossed by the curved =gluteal line= (Linea glutæa), which extends from the middle of the inner border toward the external angle. This surface gives attachment to the middle and deep gluteal muscles.

[Illustration:]

FIG. 60.—OSSA COXARUM OF MARE, DORSAL VIEW.

_O.il._, Ilium; _O.p._, pubis; _O.is._, ischium; _A.o.i._, wing of ilium; _C.o.i._, shaft of ilium; _Cr.o.i._, anterior border (crest) of ilium; _1_, obturator foramen; _2_, acetabulum; _3_, internal angle of ilium; _4_, external angle of ilium; _5_, gluteal line; _6_, psoas tubercle; _7_, _8_, acetabular and symphyseal branches of pubis; _9_, _10_, acetabular and symphyseal branches of ischium; _12_, lesser sciatic notch; _13_, ischial arch; _14_, great sciatic notch; _15_, symphysis pelvis; _17_, ilio-pectineal eminence; _18_, anterior borders of pubic bones; _19_, posterior gluteal line. (Struska, Anat. d. Haustiere.)]

The =pelvic surface= (Facies pelvina) faces in the opposite direction; it is convex, and consists of two distinct parts. The inner triangular part (Pars articularis) is roughened for ligamentous attachment, and bears an irregular facet, the =auricular surface= (Facies auricularis), for articulation with the sacrum. The outer quadrilateral part (Pars iliaca) is in general smooth. It is crossed by the =ilio-pectineal line= (Crista iliopectinea), which begins below the auricular surface and is continued on the shaft of the bone to join the anterior border of the pubis. The line is interrupted by furrows for the iliaco-femoral vessels, and below these it bears the =psoas tubercle= (Tuberculum psoadicum), which gives attachment to the psoas minor muscle. The iliacus muscle is attached to the surface external to the ilio-pectineal line.

The =anterior border= or =crest= (Crista iliaca) is concave, thick, and rough.

The =internal border= is deeply concave; its middle part forms the lower boundary of the =great sciatic foramen=, and it is continuous behind with the =superior ischiatic spine=.

The =external border= is concave and in great part rough. Its fore part is crossed by grooves for the ilio-lumbar vessels, which are continued on the pelvic surface. The =nutrient foramen= is usually situated on or near the posterior part of this border.

[Illustration:]

FIG. 61.—OSSA COXARUM OF MARE, VENTRAL VIEW.

_D_, Ilium; _Sch._, pubis; _S_, ischium; _a_, anterior border (crest) of ilium; _b_, internal angle of ilium; _c′_, external angle of ilium; _d_, great sciatic notch; _e_, external border of ilium; _f_, iliac surface; _g_, linea arcuata; _h_, rough ligamentous area; _i_,

auricular surface; _k_, ilio-pectineal line; _l_, psoas tubercle; _m_, transverse branch, and _n_, symphyseal branch of pubis; _o_, _o′_, symphysis pelvis; _p_, anterior border of pubis (pecten); _q_, tuberculum pubicum; _r_, ilio-pectineal eminence; _s_, tuber ischii; _t_, ischial arch; _u_, lesser sciatic notch; _v_, acetabular branch, and _w_, symphyseal branch of ischium; _x_, obturator foramen; _y_, articular surface of acetabulum; _z_, fossa acetabuli; _1_, groove for ilio-lumbar artery; _2_, groove for iliaco-femoral artery; _3_, subpubic groove; _4_, depression for inner tendon of origin of rectus femoris; _5_, rough area for attachment of adductor muscles. (Ellenberger-Baum, Anat. d. Haustiere.)]

The =internal= or =sacral angle= (Tuber sacrale) curves upward and a little backward close to the first sacral spine, and forms here the highest point of the skeleton. It is somewhat thickened and rough.

The =external= or =coxal angle= (Tuber coxæ) forms the basis of the point of the hip. It is a large quadrangular mass, narrow in its middle, and enlarged at either end, where it bears a pair of tuberosities. It is roughened for muscular attachment.

The =posterior= or =acetabular angle= meets the other two bones at the acetabulum, of which it forms about two-fifths. Its prominent upper border forms part of the =superior ischiatic spine=, which is roughened externally, smooth internally. Two depressions above and in front of the acetabulum give attachment to the tendons of origin of the rectus femoris muscle. This angle is connected with the ala or wide part of the bone by a constricted part, often termed the =shaft=. The latter is of three-sided prismatic form. Its external surface is convex and rough, and gives attachment to the deep gluteus muscle. Its pelvic surface is smooth and is grooved for the obturator vessels and nerves. Its ventral surface is crossed by vascular grooves, below which is a rough area, bounded internally by the psoas tubercle.

THE ISCHIUM

The =ischium= (Os ischii) forms the posterior part of the ventral wall or floor of the bony pelvis. It slopes a little downward and inward, but is practically horizontal in the longitudinal direction. It is irregularly quadrilateral, and may be described as having two surfaces, four borders, and four angles.

The =superior= or =pelvic surface= (Facies pelvina) is smooth and slightly concave from side to side.

The =inferior surface= (Facies externa) is nearly flat, and is in great part roughened for the attachment of the adductor muscles.

The =anterior border= forms the posterior margin of the obturator foramen.

The =posterior border= is thick and rough. It slopes obliquely inward and forward to meet the border of the other side, forming with it the =ischial arch= (Arcus ischiadicus).

The =internal border= meets the opposite bone at the symphysis.

The =external border= is thick and rounded, but concave in =its length=; it forms the =lesser sciatic notch=, the lower boundary of the lesser sciatic foramen.

The =antero-internal angle= or =symphyseal branch= (Ramus symphyseos) meets the pubis, with which it forms the inner boundary of the obturator foramen.

The =antero-external angle= or =acetabular branch= joins the other two bones at the acetabulum, of which it forms more than half. Superiorly it bears part of the =superior ischiatic spine= (Spina ischiadica), and internally it is grooved for the obturator vessels.

The =postero-external angle= is a thick three-sided mass, the =tuber ischii= (Tuber ischiadicum); its lower border is the =inferior ischiatic spine=, to which the biceps femoris and semitendinosus muscles are attached.

THE PUBIS

The =pubis= (Os pubis) is the smallest of the three parts of the os coxæ. It forms the anterior part of the pelvic floor, and may be described as having two surfaces, three borders, and three angles.

The =superior= or =pelvic surface= (Facies pelvina) is convex in the young subject and the stallion, concave and smooth in the mare and usually in the gelding also. The urinary bladder rests on it.

The =inferior= or =ventral surface= (Facies externa) is convex, and in great part rough for muscular attachment. Near the anterior border it is crossed by the =subpubic groove=, the inner part of which is occupied by a large vein, the outer part by the pubo-femoral ligament.

The =anterior border= is thin in its inner part (except in the young subject and the stallion), forming the pecten ossis pubis. Externally it bears the rough =ilio-pectineal eminence= (Eminentia iliopectinea), beyond which it is continuous with the ilio-pectineal line.

The =internal border= joins the opposite bone at the symphysis pubis.

The =posterior border= forms the anterior margin of the obturator foramen, and is marked externally by the obturator groove.

The =internal angle= meets its fellow at the anterior end of the symphysis. This part is very thick in the young subject and the stallion, but in the mare, and usually in the gelding also, it becomes thin with advancing age.

The =external= or =acetabular angle= joins the ilium and ischium at the acetabulum.

The =posterior angle= joins the ischium, with which it forms the inner boundary of the obturator foramen.

The =pubis= may conveniently be regarded as consisting of two branches which meet at a right angle; these are termed the =transverse= or =acetabular branch= (Ramus acetabularis) and the =longitudinal= or =symphyseal branch= (Ramus symphysecs).

The =acetabulum= is a cotyloid cavity which lodges the head of the femur. It faces downward and outward, and consists of an articular and a non-articular part. The =articular part= (Facies lunata) is crescentic, and is cut into internally by the non-articular part, which lies at a lower level, and is termed the =acetabular fossa= (Fossa acetabuli). The inner part of the rim is correspondingly cut into by the =acetabular notch= (Incisura acetabuli), which is converted into a foramen by the transverse ligament in the fresh state, and transmits the pubo-femoral and round ligaments to the head of the femur.

The =obturator foramen= (Foramen obturatum) is situated between the pubis and ischium. It is oval in outline, the longer axis being directed forward and outward. Its margin is grooved antero-externally for the obturator nerve and vessels.

[Illustration:

FIG. 62.—OSSA COXARUM OF STALLION, DORSAL VIEW. (After Ellenberger-Baum, Anat. für Künstler.)]

=Development.=—Each division of the os coxæ ossifies from one chief center. The center for the ilium appears first near the acetabulum, followed quickly by one for the ischium, and a little later by the pubic center. Secondary centers appear for the crest and external angle of the ilium, the tuber and posterior border of the ischium, and the acetabular part of the pubis. The pubis and ischium are united at birth or soon after, but are not fused with the ilium until the second year. The epiphyseal parts fuse with the main mass at four and a half to five years of age.

The acetabular part of the pubis ossifies from a separate center. It is most distinct in the embryo at three months, and is often called the os acetabuli. Martin says that the ilium has a center for the acetabular part, one for the shaft and wing, and a third for the crest. He also states that there is a special center for the acetabular part of the ischium, and a transitory nucleus in the symphyseal part of the pubis.

THE PELVIS

The =bony pelvis= is composed of the ossa coxarum, the sacrum, and the first three coccygeal vertebræ. The =dorsal wall= or =roof= is formed by the sacrum and first three coccygeal vertebræ, and the =ventral wall= or =floor= by the pubic and ischial bones. The =lateral walls= are formed by the ilia and the acetabular part of the ischia. The defect in the skeleton here is supplied in the fresh state by the sacro-sciatic ligaments and semimembranosus muscles.

The =anterior aperture= or =inlet= (Apertura pelvis cranialis) is bounded by the =terminal line= (Linea terminalis) or brim, composed of the base of the sacrum dorsally, the ilio-pectineal lines laterally, and the anterior border of the pubis ventrally. It is almost circular in the mare, semi-elliptical in the stallion, and faces obliquely downward and forward. It has two principal diameters. Of these, the =conjugate= or =sacro-pubic diameter= (Conjugata) is measured from the sacral promontory to the anterior end of the symphysis. The =transverse diameter= (Diameter transversa) is measured at the greatest width, _i. e._, just above the psoas tubercle.

The =posterior aperture= or =outlet= (Apertura pelvis caudalis) is much smaller and is very incomplete in the skeleton. It is bounded above by the third coccygeal vertebra and below by the ischial arch; in the fresh state it is completed laterally by the sacro-sciatic ligament and the semimembranosus muscle.

The =axis= of the pelvis is an imaginary line drawn through the centers of the inlet, cavity, and outlet.

=Sexual Differences.=—Marked differences exist in the size and form of the pelvis in the two sexes. The average =conjugate diameter= is about 9½ inches (ca. 23 to 24 cm.) in the mare, 7½ inches (ca. 18 to 20 cm.) in the stallion. The =transverse diameter= of the inlet averages about 9 inches (ca. 22 to 23 cm.) in the mare, and 8 inches (ca. 20 cm.) in the stallion. The =obliquity= of the inlet is greater in the female; the difference is indicated by the fact that a vertical plane from the pecten cuts the fourth sacral segment in the female, the second in the male. The =outlet= is also larger in the mare, the =ischial arch= being about one-third wider than in the stallion. The =cavity= is much more roomy in the female; the transverse diameter between the middles of the superior ischiatic spines is about 8 inches (20 cm.) in the mare, 6 inches (15 cm.) in the stallion. The pubic part of the =floor= in the female is concave and lies considerably lower than the ischiatic part, which is wide and relatively flat. In the stallion the pubis is very thick centrally, and this part of the floor is convex, while the ischial part is relatively narrow, and is concave from side to side. The =obturator foramina= are correspondingly larger in the female. The ilium is shorter, and the greater sciatic notch deeper and narrower in the male. The pelvis of the gelding, when castration has been performed early, resembles that of the mare; otherwise the male characters appear to be retained to a large degree.

THE FEMUR

The =femur= or thigh bone (Os femoris) is the largest and most massive of the long bones. It extends obliquely downward and forward, articulating with the acetabulum above and the tibia and patella below. It presents for examination a shaft and two extremities.

The =shaft= or =body= (Corpus femoris) is in general cylindrical, but flattened behind, and larger above than below. The =anterior= and =lateral surfaces= are continuous and strongly convex from side to side; there is often a central vertical rough line on the proximal part, but otherwise these surfaces are smooth. They are covered by the quadriceps femoris muscle. The =posterior surface= is wide, flat, and smooth in its proximal fourth. Below this part there is a rough elevation externally for the attachment of the femoral tendon of the biceps femoris, and a rough line internally to which the quadratus femoris is attached. The middle third is narrower, and is rough for the attachment of the adductor muscle. Just below this area an oblique groove crosses the surface, indicating the position of the femoral vessels. The =internal border= bears on its proximal part the =internal trochanter= or =trochanter minor=, a thick rough ridge, to which the ilio-psoas muscle is attached. From this a rough line curves up to the front of the neck and indicates the limit of the attachment of the vastus internus muscle. A narrow rough area about the middle gives attachment to the pectineus muscle, and the =nutrient foramen= is usually found just in front of this mark. The =supracondyloid crest= is situated below the groove for the femoral vessels, and gives origin to the inner head of the gastrocnemius. The =external border= is prominent in its upper part, and bears at the junction of its proximal and middle thirds the =external= or =third trochanter= (Trochanter tertius); this process is curved forward, and furnishes insertion to the tendon of the superficial gluteus muscle. At the lower part is found the =supracondyloid= or =plantar fossa= (Fossa plantaris), in which the superficial flexor arises; it is bounded externally by a thick rough margin, to which the outer head of the gastrocnemius muscle is attached.

intercondyloid fossa. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =proximal extremity= (Extremitas proximalis) is large and consists of the head, neck, and great trochanter. The =head= (Caput femoris) is placed at the inner side and is directed inward, upward, and somewhat forward. It is approximately hemispherical and articulates with the acetabulum. It is cut into internally by a deep notch, the =fovea capitis=, in which the pubo-femoral and round ligaments are attached. The articular surface is surrounded by a distinct margin. The =neck= (Collum femoris) is most distinct in front and internally. The =great trochanter= (Trochanter major) is situated externally; it presents three features. The =anterior part= or =convexity= is situated opposite to the head and rises little above the level of the latter; it gives attachment to the deep gluteus muscle, and in the fresh state its outer surface is coated with cartilage, over which a tendon of the middle gluteus passes, to be inserted into the =crest=, which is placed below and behind the convexity. The =posterior part= or =summit= is separated from the convexity by a notch; it is situated behind the plane of the head and rises to a much greater height. It furnishes insertion to part of the middle gluteus muscle. Its posterior border is continued downward as the =trochanteric ridge=, which forms the outer wall of the =trochanteric fossa=. A number of foramina are found in the concave area internal to the convexity.

[Illustration:

FIG. 66.—FRONTAL SECTION OF LEFT FEMUR OF HORSE, ANTERIOR VIEW.

The figure shows that the medullary cavity is traversed for the most part by fine bony trabeculæ.]

The =distal extremity= (Extremitas distalis) is large in both directions and comprises the trochlea in front and two condyles behind. The =trochlea= consists of two ridges separated by a groove, and forms an extensive surface (Facies patellaris) for articulation with the patella. It is very unsymmetrical; the inner ridge or lip is much wider, more prominent, and extends up higher than the external one, and the two converge below. The =condyles=, =internal= and =external= (Condylus medialis, lateralis), are separated by the deep =intercondyloid fossa= (Fossa intercondyloidea), and articulate with the condyles of the tibia and the semilunar cartilages of the stifle joint. A ridge connects each condyle with the lower part of the corresponding lip of the trochlea. The intercondyloid fossa lodges the spine of the tibia and the crucial ligaments of the stifle joint, which are attached here.

The condyles are obliquely placed, with their long axes directed downward, forward, and inward. The articular surface of the external condyle is more strongly convex from side to side than that of the inner one, and the ridge which connects it with the trochlea is much narrower.

The =internal epicondyle= (Epicondylus medialis) is a rounded prominence on the internal surface of the internal condyle, to which the internal lateral ligament and the adductor muscle are attached. The corresponding =external epicondyle= (Epicondylus lateralis) is less distinct; it presents a mark where the lateral ligament is attached, below and behind which there is a depression (Fossa musculi poplitei) in which the popliteus muscle arises. Between the external condyle and trochlea is the =extensor fossa= (Fossa extensoria), in which the tendon of origin of the anterior extensor and peroneus tertius is attached.

=Development.=—The shaft and the distal end each ossify from one center, but the proximal end has two centers, one of which is for the great trochanter. The edge of the external trochanter also has a separate center. The proximal end fuses with the shaft at three to three and a half years, the distal at about three and a half years.

[Illustration:

FIG. 67.—DISTAL EXTREMITY OF RIGHT FEMUR OF HORSE, END VIEW.]

THE TIBIA

The =tibia= is a long bone which extends obliquely downward and backward from the stifle to the hock. It articulates above with the femur, below with the tarsus, and externally with the fibula. It possesses a shaft and two extremities.

The =shaft= or =body= (Corpus tibiæ), large and three-sided above, becomes smaller and flattened in the sagittal direction below, but widens a little at the distal end. It presents for notice three surfaces and three borders. The =internal surface= (Facies medialis) is broad above, where it furnishes insertion to the internal lateral ligament and the sartorius and gracilis muscles; below this it is convex and subcutaneous. The =external surface= (Facies lateralis) is smooth and somewhat spiral. It is wide and concave in its upper part, below which it becomes narrower and slightly convex, and winds gradually to the front of the bone; near the distal end it widens a little, becomes flat, and faces forward. The =posterior surface= (Facies posterior) is flattened, and is divided into two parts

by the rough =popliteal line=, which runs obliquely from the upper part of the external border to the middle of the internal border. The triangular area above the line is occupied by the popliteus muscle, while the area below is marked by rough lines (Lineæ musculares) to which the deep flexor muscle of the digit is attached; the lines fade out below, where the surface is smooth and flat. The =nutrient foramen= is situated on or near the popliteal line. The =anterior border= is very prominent in its upper third, forming the =tibial crest= (Crista tibiæ); below it is reduced to a rough line, which ends at a small elevation near the distal end of the bone. The =internal border= (Margo medialis) is rounded in its upper half, to which the popliteus muscle is attached, and a tubercle is found on this part. The lower part is a rough line on well-marked bones. The =external border= (Crista interossea) is concave in its upper part and concurs with the fibula in the formation of the interosseous space of the leg; a smooth impression indicates the course of the anterior tibial vessels through the space to the front of the leg. Lower down the border divides and incloses a narrow triangular surface.

[Illustration:

FIG. 68.—RIGHT TIBIA AND FIBULA OF HORSE, EXTERNAL VIEW.]

The =proximal extremity= (Extremitas proximalis) is large and three-sided. It bears two lateral eminences, the =internal= and =external condyles= (Condylus medialis, lateralis). Each presents a somewhat saddle-shaped surface for articulation with the condyle of the femur and the semilunar cartilage. The =spine= or =intercondyloid eminence= (Eminentia intercondyloidea) is the central prominence, upon which the articular surfaces are continued; it consists of a high inner part and a lower outer part (Tuberculum intercondyloideum mediale, laterale). On, before, and behind the spine are the =anterior= and =posterior intercondyloid fossæ=, in which the anterior crucial ligament and the semilunar cartilages are attached. The condyles are separated behind by the deep =popliteal notch= (Incisura poplitea), on the inner side of which is a tubercle for the attachment of the posterior crucial ligament. The external condyle has an overhanging outer margin, below which is a =facet= for articulation with the fibula. The =large anterior= eminence is the =tuberosity= of the tibia (Tuberositas tibiæ). It is marked in front by a =groove=, the lower part of which gives attachment to the middle patellar ligament, and the groove is flanked by rough areas for the attachment of the internal and external patellar ligaments. A semicircular smooth =notch= (Sulcus muscularis) separates the tuberosity from the external condyle, and gives passage to the tendon of origin of the anterior extensor and the peroneus tertius.

[Illustration:

FIG. 69.—RIGHT TIBIA AND FIBULA OF HORSE, POSTERIOR VIEW.]

The =distal extremity= (Extremitas distalis) is much smaller than the proximal; it is quadrangular in form and larger internally than externally. It presents an =articular surface= (Cochlea tibiæ), which is adapted to the trochlea of the tibial tarsal bone (astragalus), and consists of two grooves separated by a ridge. The ridge and grooves are directed obliquely forward and outward, and are bounded laterally by the =malleoli=, to which the lateral ligaments of the hock joint are attached. The =internal malleolus= (Malleolus tibialis) is the more prominent of the two, and forms the anterior boundary of a groove for the tendon of the inner head of the flexor perforans. The =external malleolus= (Malleolus fibularis) is broader, and is marked by a vertical groove for the passage of the lateral extensor tendon.

[Illustration:

FIG. 70.—RIGHT TIBIA AND FIBULA OF HORSE, ANTERIOR VIEW.]

=Development.=—The tibia has the usual three chief centers of ossification and supplementary ones for the tuberosity and the external malleolus. The latter is really the distal end of the fibula; it is a separate piece at birth, and the line of union is commonly quite evident in the adult in the external articular groove. The proximal end unites with the shaft at about three and a half years, and the distal end at about two years of age.

THE FIBULA

The =fibula= of the horse is a much reduced long bone, situated along the outer side of the tibia.

The =shaft= or =body= (Corpus fibulæ) is a slender rod which forms the outer boundary of the interosseous space; it usually terminates below in a pointed end about one-half to two-thirds of the way down the external border of the tibia.

The =proximal extremity= or =head= (Capitulum fibulæ) is relatively large, and is flattened transversely. Its internal surface presents a narrow area along the upper border for articulation with the tibia. The external surface is rough and gives attachment to the external lateral ligament of the stifle joint. It has rounded anterior and posterior borders.

[Illustration:

FIG. 71.—PROXIMAL EXTREMITY OF RIGHT TIBIA OF HORSE, END VIEW.

_l.c.a._, _l.c.p._, Depressions for attachment of anterior and posterior crucial ligaments; _l_, _m_, _m_, depressions for attachment of semilunar cartilages.]

The =distal extremity= is fused with the tibia, constituting the external malleolus.

=Development.=—This resembles that of the ulna. The embryonic cartilaginous fibula extends the entire length of the leg, but does not articulate with the femur. The lower part of the shaft is usually reduced to a fibrous band. Three centers of ossification appear, one each for the shaft and the extremities. The distal end unites early with the tibia, forming the external malleolus.

It is interesting to note that in some cases the entire shaft of the fibula develops, a reversion to the condition in the Miocene ancestors of the present horse.

THE PATELLA

The =patella= is a large sesamoid bone which articulates with the trochlea of the femur. It presents for description two surfaces, two borders, a base, and an apex.

The =anterior= or =free surface= (Facies libera) is irregularly quadrilateral, convex, and rough for muscular and ligamentous attachment.

The =posterior= or =articular surface= is smaller and is triangular in outline. It presents a vertical rounded ridge, which corresponds to the groove on the trochlea of the femur, and separates two concave areas. Of the latter, the inner cavity is much the larger, and is not very well adapted to the inner lip of the trochlea; in the fresh state, however, it is completed and rendered more congruent by the curved =accessory fibro-cartilage=.

[Illustration:

FIG. 72.—FRONTAL SECTION OF RIGHT TIBIA OF HORSE, ANTERIOR VIEW.]

The =lateral borders= converge to the apex below, and each forms a prominence or angle at the base. The inner angle and the adjacent part of the border give attachment to the fibro-cartilage of the patella, which increases the articular surface. The external border is rounded and its angle is less prominent.

The =base= (Basis patellæ) faces upward and backward, and is convex transversely, concave from before backward.

The =apex= forms a blunt point directed downward.

=Development.=—The patella develops as a sesamoid bone from a single center in a cartilaginous deposit in the tendon of the quadriceps femoris muscle.

THE TARSUS

The =tarsus= or =hock= of the horse usually comprises six short bones (Ossa tarsi), but exceptionally seven are present.

THE TIBIAL TARSAL BONE

The =tibial tarsal= bone (Os tarsi tibiale, astragalus, or talus) is the inner bone of the proximal row. It is extremely irregular in form, but may be considered as offering six surfaces for description.

[Illustration:

FIG. 73.—RIGHT PATELLA OF HORSE, ANTERIOR VIEW.]

[Illustration:

FIG. 74.—RIGHT PATELLA OF HORSE, POSTERIOR VIEW.]

The =superior= and the =anterior= or =dorsal surface= are continuous, and form a =trochlea= for articulation with the distal end of the tibia. The trochlea consists of two oblique ridges with a deep groove between them, which curve spirally forward, downward, and outward. There is usually a shallow =synovial fossa= in the groove. The =inferior surface= is convex from before backward, and most of it articulates with the central tarsal; externally it has an oblique facet for the fourth tarsal, and a non-articular groove cuts into the surface to its middle. The =posterior= or =plantar surface= is oblique and extremely irregular; it presents four facets for articulation with the fibular tarsal bone; the facets are separated by rough excavated areas, and the largest fossa (Sulcus tali) forms with a corresponding one on the fibular tarsal a cavity termed the =sinus tarsi=. The =internal surface= bears on its lower part a large tuberosity, and on its upper part a small one for the attachment of the internal lateral ligament. The =external surface= is smaller than the internal, and is marked by a wide rough fossa in which the external ligament is attached.

THE FIBULAR TARSAL BONE

[Illustration:

FIG. 75.—RIGHT TARSUS AND UPPER PART OF METATARSUS OF HORSE, INTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 76.—RIGHT TARSUS AND UPPER PART OF METATARSUS OF HORSE, POSTERIOR (PLANTAR) VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =fibular tarsal= bone (Os tarsi fibulare, calcaneum, os calcis) is the largest bone of the hock. It is elongated, flattened from side to side, and forms a lever for the muscles which extend the hock joint. It consists of a body and an inner process, the sustentaculum tali.

[Illustration:

FIG. 77.—RIGHT TIBIAL TARSAL BONE OF HORSE, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

[Illustration:

FIG. 78.—RIGHT TIBIAL TARSAL BONE OF HORSE, EXTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =body= (Corpus calcanei) is enlarged at its proximal end to form the =tuber calcis= or “point of the hock.” The posterior part of this eminence gives attachment to the tendon of the gastrocnemius, while in front and laterally it furnishes insertion to tendons of the flexor perforatus, biceps, and semitendinosus muscles. The =inferior extremity= bears a concave facet for articulation with the fourth tarsal bone. The =internal surface= has on its lower part a strong process, the =sustentaculum tali=, which projects inward. The process has a large, oval, slightly concave facet in front for articulation with the tibial tarsal, and sometimes a small articular surface below for the central tarsal bone. Its plantar surface forms with the smooth inner surface of the body a groove for the deep flexor tendon (Sulcus musculi flexoris hallucis longi). Its inner surface has a prominence on the lower part for the attachment of the lateral ligament. The =external surface= of the body is flattened, except below, where there is a rough prominence for the attachment of the lateral ligament. The =anterior= or =dorsal border= is concave in its length, smooth and rounded in its upper part. About its middle is a blunt-pointed projection (Processus cochlearis) which bears facets on its inner and lower surfaces for articulation with the tibial tarsal bone, and is roughened outwardly for ligamentous attachment. Below this are two facets for the tibial tarsal, and an extensive rough fossa which concurs in the formation of the sinus tarsi. The =posterior= or =plantar border= is straight and thick, and widens a little at either end; it is rough, and gives attachment to the long plantar ligament.

[Illustration:

FIG. 83.—PROXIMAL ARTICULAR SURFACES OF LEFT METATARSAL BONES OF HORSE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE CENTRAL TARSAL BONE

The =central tarsal= bone (Os tarsi centrale, scaphoid, or navicular) is irregularly quadrilateral, and is situated between the tibial tarsal above and the third tarsal below. It is flattened from above downward, and may be described as having two surfaces and four borders. The =superior surface= is concave from before backward, and almost all of it articulates with the tibial tarsal; a non-articular depression cuts into its outer part, and sometimes there is a facet for the fibular tarsal bone on the posterior angle. The =inferior surface= is convex, and is crossed by a non-articular groove, which separates facets for articulation with the third and the first and second (fused) tarsals. The =anterior= or =dorsal border= and the =internal border= are continuous, convex, and rough. The =posterior= or =plantar border= bears two prominences, separated by a notch. The =external border= is oblique, and bears anterior and posterior facets for articulation with the fourth tarsal, between which it is excavated and rough.

[Illustration:

FIG. 84.—RIGHT TARSAL AND METATARSAL BONES OF HORSE. EXTERNAL VIEW. (After Schmaltz, Atlas d. d. Anat. d. Pferdes.)]

FIRST AND SECOND TARSAL BONES

The =first= and =second tarsal= bones (Os tarsale primum et secundum, cuneiform parvum) are usually fused in the horse, forming a bone of very irregular shape, situated in the inner and posterior part of the lower row, below the central and behind the third tarsal. It is the smallest of the tarsal bones, and may be described as having two surfaces, two borders, and two extremities. The =internal surface= faces backward and inward, and is convex. Its anterior part is ridged, and gives attachment to the internal lateral ligament, and its posterior part bears an imprint where the inner tendon of the tibialis anterior is inserted. The =external surface= is marked by a deep notch which indicates the division between the first and second tarsal elements; it bears on its anterior part a large concave facet for the central tarsal. The =superior border= is convex. The =inferior border= is broad in front, where it articulates with the large and inner small metatarsal bones. The =anterior extremity= has a small facet for articulation with the third tarsal, and bears internally a ridge or tubercle. The =posterior extremity= is a blunt point.

In some cases the first and second tarsal bones remain separate—a remarkable reversion to the condition in the early ancestors of the horse. In such specimens the first tarsal is a discoid bone, articulating above with the central, below with the small metacarpal bone. The second tarsal is quadrangular, equivalent to the thick anterior part of the bone as described above, and overlapped by the anterior part of the first tarsal.

THE THIRD TARSAL BONE

The =third tarsal= bone (Os tarsale tertium, third or great cuneiform) resembles the central, but is smaller and triangular in outline. It is situated between the central above and the large metatarsal bone below. It possesses two surfaces and three borders.

The =superior surface= is concave, and is crossed by a non-articular depression which divides it into two unequal facets; it articulates with the central tarsal. The =inferior surface= is slightly convex, and rests on the large metatarsal bone; it has an extensive central rough excavation. The =anterior= or =dorsal border= is convex and bears a rounded ridge on its inner part. The =internal border= is deeply notched and has a small facet for the second tarsal on its anterior part. The =external border= is also divided by a notch into two parts, and bears two diagonally opposite facets for articulation with the fourth tarsal. In some cases

there is a facet for the inner small metatarsal bone.

[Illustration:

FIG. 85.—CROSS-SECTIONS OF METACARPAL AND METATARSAL BONES OF HORSE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

THE FOURTH TARSAL BONE

The =fourth tarsal= bone (Os tarsale quartum, cuboid) is the outer bone of the lower row, and is equal in height to the central and third together. It is cuboid in shape and presents six surfaces.

The =superior surface= is convex from side to side, and articulates chiefly with the fibular tarsal, but to a small extent with the tibial tarsal also. The =inferior surface= rests on the large and external small metatarsal bones. The =internal surface= bears four facets for articulation with the central and third tarsal bones. It is crossed from before backward by a smooth groove, which by apposition with the adjacent bones forms the =canal of the tarsus= (Canalis tarsi) for the passage of the perforating tarsal vessels. The =anterior= or =dorsal=, =external=, and =posterior= or =plantar surfaces= are continuous and rough. A tuberosity behind gives attachment to the plantar ligament.

=Development.=—The fibular tarsal bone has two centers of ossification, one for the main mass and the other for the tuber calcis; the latter fuses with the rest of the bone at about three years of age. The first and second tarsals have separate centers, but fusion usually occurs before birth. Each of the other bones ossifies from a single center.

[Illustration:

FIG. 86.—DIGITAL BONES OF FORE LIMB OF HORSE, VOLAR ASPECT.]

[Illustration:

FIG. 87.—DIGITAL BONES OF HIND LIMB OF HORSE, VOLAR ASPECT.]

THE METATARSUS

The =metatarsal= bones (Ossa metatarsalia), three in number, have the same general arrangement as the metacarpal bones, but present some important differences. Their direction is slightly oblique, downward and a little forward.

The =large= or =third metatarsal= bone is about one-sixth longer than the corresponding metacarpal; in an animal of medium size the difference is about two inches. The shaft is more cylindrical, and is almost circular on cross-section, except in its lower part. At the upper part of its external surface there is a groove, which is directed obliquely downward and backward, and is continued by the furrow formed by the apposition of the external metatarsal bone; it indicates the course of the great metatarsal artery. A faint impression in a similar place on the inner side marks the position of the corresponding vein. The nutrient foramen is relatively higher than on the metacarpal bone. The proximal extremity is much wider from before backward than that of the metacarpal bone. Its articular surface is slightly concave, and is marked by a large central non-articular depression, continued outward by a deep notch. The greater part of the surface articulates with the third tarsal, but there is an outer facet for the fourth, and usually a small facet posterointernally for the second tarsal bone. Posteriorly there are two pairs of facets for articulation with the small metatarsal bones. The front is crossed by a rough ridge for insertion, which becomes larger and turns downward on the outer side behind the vascular groove. The distal extremity closely resembles that of the corresponding metacarpal bone.

In some cases the lower part of the shaft is bent backward somewhat. The articular surface extends a little higher behind than in the case of the metacarpal bone. The large metatarsal bone is even more strongly constructed than the metacarpal. The shell of compact substance is very thick in the middle of the shaft, especially in front and internally.

The =small metatarsal= bones are a little longer than the corresponding metacarpals. The =external= (fourth) =metatarsal= is relatively massive, especially in its upper part. The head is large and outstanding, and bears two facets above for the fourth tarsal, and two in front and internally for articulation with the large metatarsal; elsewhere it is roughened for attachment. The =internal= (second) =metatarsal= is much more slender than the outer one, especially in its upper part. The head bears two facets above for the first and second tarsals, and sometimes one for the third tarsal.

THE PHALANGES AND SESAMOIDS

The axis of the phalanges of the hind limb is about five degrees less oblique than that of the fore limb, and the chief differences in the form and size of the bones are as follows:

The =first phalanx= is a little shorter, wider above, and narrower below.

The =second phalanx= is narrower and slightly longer.

The =third phalanx= is narrower, the angle of inclination of the wall surface is a little (ca. 5 degrees) greater, the sole surface is more concave, and the wings are less prominent and closer together.

The =proximal sesamoids= are a little smaller, except in thickness. The =third sesamoid= or =navicular bone= is narrower and shorter.

SKELETON OF THE OX

VERTEBRAL COLUMN

The vertebral formula is C_{7}T_{13}L_{6}S_{5}Cy_{18–20}.

The =cervical vertebræ= are much shorter than those of the horse and are smaller in their other dimensions. The =articular processes= are smaller than in the horse, and a plate of bone connects each two of the same side. The transverse processes of the third, fourth, and fifth are double; the upper part projects backward, and is short and stout; the lower part is directed downward and forward, and is longer and more plate-like. The lower part of the sixth transverse process is a large, thick, quadrilateral and almost sagittal plate, directed downward. The seventh transverse process is single, short, and thick, and presents no foramen transversarium; it is in series with the upper part of the preceding processes. The =spinous processes= are well developed, and increase in height from before backward. They are directed upward and forward, with the exception of the last, which is nearly vertical and is about four or five inches (ca. 10 to 12 cm.) in height. The summit of that of the third bone is usually bifid. The =ventral spines= are prominent and thick in their posterior part; they are absent on the last two.

The =atlas= has a large rough =tuberosity= on its dorsal arch. The =ventral arch= is very thick. The =wings= are less curved than in the horse, and the foramen transversarium (posterior foramen) is absent. The cavities for the occipital condyles are divided into upper and lower parts by a non-articular area, and are separated by a narrow interval below. The =posterior articular surfaces= are flattened behind and are continued into the vertebral canal, forming an extensive area for the odontoid process of the axis.

The =axis= is short. The =spine= projects a little in front, and increases in height and thickness behind; its posterior border descends abruptly. The =odontoid process= (dens) is wide, and its upper surface is deeply concave from side to side. The =intervertebral foramen= is circular and not so close to the anterior border of the arch as in the horse. The =posterior notches= are not so deep. The =transverse processes= are stouter, but the =foramen transversarium= is small and sometimes absent.

The =thoracic vertebræ=, thirteen in number, are larger than those of the horse. The =bodies= are longer and are distinctly constricted in the middle. They bear a thin-edged ventral crest. The =arches=—in addition to the usual notches, which are shallow—are perforated in the posterior part by a foramen. The =transverse processes= are thick and strong, and bear rounded mammillary processes (except at the posterior end of the series); the last two, although prominent, do not always articulate with the ribs. The =spinous processes= are long. The first is much higher than in the horse, the next two are usually the most prominent, and behind this there is a very gradual diminution in height. The backward slope, slight at first, increases to the tenth; the last is vertical and lumbar in character. The summit is usually pointed on the first, and the thickening on those further back is less than in the horse. The width diminishes from the fifth to the eleventh usually. Both borders of the spines are in general thin and sharp, but the last three or four sometimes have thick posterior margins.

cartilage; _x_, wing of atlas; _1_, scapula; _1′_, cartilage of scapula; _2_, spine of scapula; _3_, acromion; _4_, humerus; _4′_, external condyle of humerus; _5_, external tuberosity of humerus; _6_, deltoid tuberosity; _7_, ulna; _8_, olecranon; _9_, radius; _10_, carpus; _11_, accessory carpal bone; _12_, metacarpus; _13_, phalanges; _14_, sternum; _14′_, manubrium; _14″_, xiphoid cartilage; _15_, ilium; _16_, external angle of ilium; _16′_, internal angle of ilium; _17_, tuber ischii; _18_, femur; _19_, trochanter major; _20_, patella; _21_, tibia; _21′_, external condyle of tibia; _22_, tarsus; _23_, distal end of fibula; _24_, tuber calcis; _25_, metatarsus; _26_, phalanges. (After Ellenberger-Baum, Anat. für Künstler.)]

The =lumbar vertebræ=, six in number, are much longer than in the horse. The =bodies= are much constricted in the middle, expanded at either end, and bear rudimentary ventral crests. The fourth and fifth are usually the longest. The =intervertebral foramina= are often double in the anterior part of the series, and are very large further back. The =articular processes= are large, and their facets are more strongly curved than in the horse. The =transverse processes= all curve forward. They are separated by considerable intervals, and form no articulations with each other or with the sacrum. Their borders are thin and irregular, and often bear projections of variable size and form. The first is the shortest and the length increases to the fifth, the last being considerably shorter. The =spinous processes= are relatively low and wide, the last being the smallest; their summits are moderately thickened.

The =sacrum= is longer than that of the horse. It consists originally of five segments, but fusion is more complete and involves the spinous processes, which are united to form a =median sacral crest=, with a convex thick and rough margin. =A lateral crest= is formed by the fusion of the articular processes. The =pelvic surface= is concave in both directions, and is marked by a central =groove=, which indicates the course of the middle sacral artery. The =inferior sacral foramina= are large. The =wings= are quadrangular, short, compressed from before backward, and high dorso-ventrally. They have an extensive anterior surface, which is concave from side to side, and non-articular. The posterior surface is rough, and bears a triangular area below for articulation with the ilium. The body of the first segment is very wide, and the entrance to the sacral canal correspondingly wide and low. The =anterior articular processes= are large, and are concave and semicylindrical in curvature internally. The =lateral borders= are thin, sharp, and irregular. The =apex= is wider than in the horse, and the posterior end of the crest forms a pointed projection over the opening of the sacral canal.

The =coccygeal vertebræ= are longer and better developed than in the horse. The first five or six have complete arches and spinous processes. The transverse processes are relatively large in the anterior part of the series, in which there are also anterior articular processes (which do not articulate), and a pair of ventral spines which form a hæmal groove for the middle coccygeal artery.

Vertebral curves: The cervical curve is very slight and is concave dorsally. The thoracic and lumbar regions form a gentle curve, concave ventrally. The promontory is more pronounced than in the horse, especially in subjects in which the sacrum is inclined upward behind. Another promontory occurs at the junction of the sacrum and first coccygeal vertebræ.

Length: The following table gives the lengths of the regions of a shorthorn cow of medium size:

Cervical 47 cm. Thoracic 75 cm. Lumbar 40 cm. Sacral 24 cm. Coccygeal 75 cm. ———————— 261 cm.

Variations: Sometimes fourteen thoracic vertebræ and fourteen pairs of ribs are present; reduction to twelve with the normal number of lumbar vertebræ is very rare. According to Franck, there are sometimes seven lumbar vertebræ with the normal number in the thoracic region. The number of coccygeal vertebræ may vary from sixteen to twenty-one.

THE RIBS

Thirteen pairs of ribs are normally present, of which eight are sternal and five asternal. They are in general longer, wider, flatter, less curved, and less regular in form than in the horse. The eighth, ninth, and tenth are the longest and widest. The width of most of the ribs increases considerably in the middle, and the breadth of the intercostal spaces is correspondingly diminished. The neck is long, and forms (except in the posterior part of the series) a smaller angle with the shaft than in the horse. The articular surface of the tubercle is concave transversely, except on the last two or three, where the facet is small and flat or absent. The lower ends of the second to the tenth or eleventh inclusive form diarthrodial joints with the costal cartilages. The first costal cartilages are very short; they articulate by their internal surfaces with the sternum, but not with each other.

The presence of a fourteenth rib is not very rare. It is usually floating and may correspond to an additional thoracic vertebra or to the first lumbar. Reduction of the thirteenth is more common. The eighth cartilage often does not reach the sternum, but articulates

with the seventh.

The =sternum= consists of seven sternebræ, most of which are developed from two lateral centers. It is wider, flatter, and relatively longer than in the horse, and the ventral crest or “keel” is absent. The manubrium is somewhat wedge-shaped and laterally compressed. Its base forms a diarthrodial joint with the body of the bone, and laterally it bears extensive facets for articulation with the first pair of costal cartilages. The body widens from before backward, but behind the last pair of costal facets it becomes much narrower. The ventral surface is prominent on the second and third segments, concave further back. The lateral borders are notched for the passage of vessels. The cariniform cartilage is absent. The xiphoid cartilage is like that of the horse but is smaller.

THE THORAX

The bony thorax is shorter than in the horse. The inlet is higher. The roof is short, and the floor wider and relatively longer. The transverse diameter is wider in the posterior part. The summits of the spinous processes are almost in a straight line from the second thoracic to the middle of the lumbar region.

BONES OF THE SKULL

BONES OF THE CRANIUM

The =occipital bone= is situated in the lower part only of the posterior surface of the skull, and is separated from the highest part (the frontal eminence) by the parietal and interparietal bones. The supraoccipital, interparietals, and parietals fuse before birth or soon after, and the mass so formed is separated from the lateral parts of the occipital bone by a transverse suture in the skull of the calf. Above this suture is a central tuberosity, to which the ligamentum nuchæ is attached, and the surface on either side is depressed and rough for muscular attachment. Below the suture the bone is much wider than that of the horse. The foramen magnum is wide, so that the condyles are further apart except below. The paramastoid processes are short and wide and are bent inward. Two constant foramina are found in the condyloid fossa; the anterior one is the hypoglossal, the other (sometimes double) conducts a vein from the =condyloid canal=. The latter passes upward from a foramen on the inner side of the condyle and opens into the parieto-temporal canal. The cranial surface of the supraoccipital presents a central depression, and above this is a variable but never very pronounced eminence, which corresponds to the tentorium osseum of the horse. On either side is a groove leading to the parieto-temporal canal. The basilar process is short and wide; its cranial surface is deeply concave, and the internal spheno-occipital crest is prominent. Two large tubercles below mark the junction with the sphenoid. The foramen lacerum is short and very narrow. In the adult animal the bone is excavated to contain an air-cavity which is regarded as a part of the frontal sinus.

The =sphenoid bone= is short. The cranial surface of the body presents a deep sella turcica, in front of which it rises abruptly. The high anterior part bears a central ridge (Rostrum sphenoidale), which joins the crista galli of the ethmoid. Two foramina occur on either side. Of these, the large anterior one is equivalent to the foramen rotundum, lacerum orbitale, and patheticum of the horse. The posterior one is the =foramen ovale=, which transmits the inferior maxillary nerve. The orbital wing is thick and is overlapped by the frontal in such manner as to appear externally to divide into two branches; the anterior part joins the ethmoid close to the sphenopalatine foramen, and contains a small sinus which communicates with an ethmoidal meatus. The temporal wing is small, but forms a prominent thick pterygoid crest. The pterygoid process is wide, and the pterygoid or alar foramen is absent. The sphenoidal sinus is absent in the calf and small in the adult; it communicates by one or two small openings with an ethmoidal meatus, and so with the nasal cavity.

(After Ellenberger-Baum, Anat. für Künstler.)]

The =ethmoid bone= has an extensive perpendicular plate. The lateral mass consists of five endoturbinals and eighteen ectoturbinals (Paulli). The largest ethmoturbinal is so extensive as to be termed a third or middle turbinal bone; it projects forward between the upper and lower turbinals. The lamina papyracea appears to a small extent externally in the pterygo-palatine fossa, forming part of the upper margin of the sphenopalatine foramen.

The =interparietals= are primitively paired, but unite before birth. As already mentioned, fusion occurs before or shortly after birth with the parietals and supraoccipital. No distinct tentorium osseum is present.

[Illustration:

(Ellenberger-Baum, Anat. d. Haustiere.)]

The =parietal bones= do not enter into the formation of the roof of the cranium. They constitute the upper part of the posterior wall, and bend sharply forward along the lateral wall, forming part of the wall of the temporal fossa. The line of inflection is marked by the prominent =parietal crest=, which is continuous with the temporal crest below. The parietals are excavated to form part of the frontal sinuses in the adult animal.

The condition in the young subject is as follows: The two parietals are united with each other and also with the interparietal and supraoccipital. The resulting mass is somewhat horseshoe-shaped. Its occipital part (Planum occipitale) forms the greater part of the posterior wall of the cranium and bears about its center the tuberosity for the attachment of the ligamentum nuchæ. From either side of this a line curves outward, and divides the surface into an upper smooth area and a lower area which is rough for muscular attachment. The upper border joins the frontal bone and concurs in the formation of the frontal eminence. The temporal parts (Plana temporalia) are much smaller and are concave externally; they join the frontal above and the squamous temporal below.

_13_, Basi-occipital; _13″_, paramastoid or styloid process; _13■_, occipital condyle; _24′_, incisor teeth; _28_, body of mandible; _31_, condyle of mandible; _32_, ventral tubercle of atlas. (After Ellenberger-Baum, Anat. für Künstler.)]

The =frontal bones= are very extensive, forming about one-half of the entire length of the skull, and all of the roof of the cranium. The posterior borders form with the parietals a large central =frontal eminence= (Torus frontalis), the highest point of the skull. At the junction of the posterior and the lateral borders are the =processus cornu= or “horn-cores,” for the support of the horns. These processes are of elongated conical form, and vary greatly in size, length, curvature, and direction. The external surface is rough and porous, marked by numerous grooves and foramina; in the fresh state they are covered by the matrix of the horns. The base has a constriction, the neck. The interior is excavated to form a number of irregular intercommunicating spaces, divided by bony

septa, and communicating with the frontal sinus. In the polled breeds these processes are absent, the skull is narrower in this region, and the frontal eminence more pronounced. The supraorbital process is situated about half-way between the anterior and posterior margins; it is short and joins the frontal process of the malar bone. The supraorbital foramen (often double) is situated about an inch inward from the root of the process; it is the external orifice of the =supraorbital canal= (Canalis supraorbitalis), which passes downward and forward into the orbit. The foramen is in the course of the =supraorbital groove= (Sulcus supraorbitalis), which marks the course of the frontal vein. The anterior ends of the naso-frontal parts form a notch which receives the nasal bones, and sutural or Wormian bones are often found at this junction (naso-frontal suture). The orbital part is extensive; it is perforated behind by the orbital opening of the supraorbital canal, and below by the ethmoidal or internal orbital foramen. It does not articulate with the palatine, from which it is separated by the orbital wing of the sphenoid. The temporal part is also more extensive than in the horse. The frontal sinus is very extensive, being continued into the parietals and occipital, and the horn processes when present.

The =squamous= and =petrous parts= of the =temporal bone= fuse early—in fact, union is nearly complete at birth. The squamous part is relatively small. Its external surface is divided into two parts by the prominent temporal crest, which is continuous with the parietal crest above and turns forward below, ending at a tubercle above the external auditory meatus. The part behind the crest faces backward, and is partly free, partly united with the occipital. The area in front of the crest is concave and enters into the formation of the temporal fossa; it is perforated by foramina which communicate with the parieto-temporal canal. The zygomatic process is much shorter and weaker than in the horse, and articulates with the malar only. The condyle is convex in both directions. The postglenoid process is less prominent, and behind it is the chief external opening of the parieto-temporal canal. The internal surface is almost completely overlapped by the parietal and sphenoid. The petrous part proper is small, but the tympanic part is extensive. The external auditory meatus is smaller than in the horse and is directed outward. From it a plate projects downward and helps to inclose the deep depression in which the hyoid process is placed. Behind this plate is the stylo-mastoid foramen. The muscular process is large and often bifid at its free end. The bulla ossea is large and laterally compressed. It is separated from the occipital bone by a narrow opening which is equivalent to part of the foramen lacerum basis cranii of the horse. The parieto-temporal canal is formed entirely in the temporal bone. The facial canal, on the other hand, is bounded partly by the occipital bone.

BONES OF THE FACE

The =maxilla= is shorter but broader and relatively higher than in the horse. Its external surface bears instead of the facial crest a rough =facial tuberosity= (Tuber malare), placed above the third cheek tooth; a rough curved line often extends from it to the upper part of the malar bone. The infraorbital foramen—often double—is situated above the first cheek tooth. The tuber maxillare is small, laterally compressed, and usually bears a small pointed process (Processus pterygoideus). The zygomatic process is very small. The interalveolar border is concave, and there is no alveolus for a canine tooth. The palatine process is wider, but somewhat shorter than in the horse. It incloses a large air-space, which is continuous behind with a like cavity in the horizontal part of the palate bone, forming the =palatine sinus=. This communicates externally (over the infraorbital canal) with the maxillary sinus; in the macerated skull it communicates with the nasal cavity by a large oval opening, which is closed by mucous membrane in the fresh state. A median septum separates the two palatine sinuses. The alveoli for the cheek teeth increase in size from before backward. The maxillary sinus proper is small and is undivided. The maxillary foramen is a narrow fissure, deeply placed at the inner side of the lacrimal bulla. The maxilla takes no part in the formation of the palatine canal. Sutural (or Wormian) bones may be found at its junction with the lacrimal and malar bones.

The body of the =premaxilla= is thin and flattened, and has no alveoli, since the canine and upper incisor teeth are absent. A deep notch takes the place of the foramen incisivum. The nasal process is short, convex externally, and is not closely attached to the nasal bone; the space between the two processes is greater than in the horse. The palatine process is narrow and is grooved on its nasal surface for the septal cartilage and the vomer. The palatine cleft is very wide.

The =palatine bone= is very extensive. The =horizontal part= forms one-fourth or more of the hard palate. The anterior palatine foramen opens near the junction with the maxilla, about half an inch from the median palatine suture and crest. =Accessory palatine foramina= are also present. The palatine groove is usually not very distinct. The palatine canal is formed entirely in this part, and there is no articulation with the vomer. A rounded ridge occurs on the nasal side of the median suture. The interior is hollow, forming part of the palatine sinus. The =perpendicular part= is an extensive, quadrilateral, thin plate, which forms the posterior part of the lateral wall of the nasal cavity and in part bounds the narrow posterior nares. Its internal surface is nearly flat, and is smooth and free, except behind, where it is overlapped by the pterygoid bone. The external surface is attached to a small

extent to the pterygoid process behind, and is free elsewhere. The sphenopalatine foramen is a long elliptical opening, formed by a deep notch in the upper edge of the palate bone and completed by the ethmoid and sphenoid. The edge behind this foramen articulates with the orbital wing of the sphenoid, not the frontal as in the horse.

[Illustration:

FIG. 93.—MEDIAN SECTION OF SKULL OF OX, WITHOUT THE MANDIBLE.

The mucous membrane is retained. The septum nasi is removed. _a_, Superior meatus; _b_, middle meatus, with _b′_ and _b″_, its upper and lower divisions; _c_, inferior meatus; _d_, superior turbinal; _e_, superior turbinal fold; _f_, inferior turbinal; _g_, alar fold; _h_, inferior turbinal fold; _i_, lateral mass of ethmoid (ethmoturbinals); _i′_, large ethmoturbinal or middle turbinal; _k_, frontal sinus; _l_, sphenoidal sinus; _m_, cranial cavity; _n_, palatine sinus; _o_, nasal bone; _o′_, parietal cartilage; _p_, palate process of maxilla; _q_, palate bone (horizontal part); _1_, sphenoid bone; _2_, _3_, inner and outer plates of frontal bone; _4_, _4′_, outer and inner plates of parietal bone; _5_, _5′_, occipital bone; _5″_, condyloid and hypoglossal foramina; _6_, paramastoid or styloid process; _6′_, occipital condyle; _7_, petrous temporal bone; _7′_, internal auditory meatus; _8_, squamous temporal bone; _9_, muscular process; _10_, pterygoid bone (hamulus). (After Ellenberger, in Leisering's Atlas.)]

The =pterygoid bone= is wider than in the horse, and forms the greater part of the lateral boundary of the posterior nares. Its outer surface is almost entirely united to the palate bone and the pterygoid process, but a small part is free in the pterygo-palatine fossa. The hamulus is distinctly hook-like, thin, and sharp.

The =nasal bone= is little more than half the length of that of the horse. It is straight in its length, but strongly curved from side to side. It does not fuse laterally with the adjacent bones, even in old age. The posterior extremity is pointed and fits into the notch between the frontal bones. The anterior end is broader, and is divided into two parts by a deep notch. In old animals there is a small extension of the frontal sinus into this bone.

The =lacrimal bone= is very large. The extensive facial part is concave in its length, and bears no lacrimal tubercle. The orbital margin is marked by several notches. The orbital part forms below the remarkable =lacrimal bulla=; this is a large and very thin-walled protuberance, which bulges backward into the lower part of the orbit, and contains an extension of the maxillary sinus. The lacrimal fossa is small, and is just behind the orbital margin.

The =malar bone= is relatively long. The facial surface is extensive; it bears a curved crest (Crista facialis) just below the orbital margin, and below this it is concave from above downward. The zygomatic process divides into two branches; of these, the frontal process turns upward and backward and joins the supraorbital process of the frontal bone; the temporal process continues backward, and is overlapped by the zygomatic process of the temporal bone, completing the zygomatic arch.

The =superior turbinal bone= is less cribriform and fragile than in the horse, and is thickest in its middle, small at either end. It is attached to the turbinal crest of the nasal bone, and curves downward, outward, and upward to be applied outwardly to the frontal and lacrimal bones. It thus incloses a cavity which communicates with the middle meatus nasi. (In the macerated skull it opens into the frontal sinus, but this communication is closed by mucous membrane in the fresh state.)

The =inferior turbinal bone= is shorter but much broader than in the horse. It is attached to the maxilla by a basal lamella about an inch (ca. 2 to 3 cm.) wide, which slopes downward and inward. At the inner edge of this it splits into two plates which are rolled in opposite directions, and inclose two separate cavities, subdivided by several septa. The upper one opens into the middle meatus, the lower one into the inferior meatus nasi.

The =vomer= forms a wider and deeper groove than in the horse. Its anterior end rests in a groove formed by the ends of the palatine processes of the premaxillæ. The anterior third of its thin lower edge fits into the nasal crest of the maxilla; behind this it is free and separated by a considerable interval from the nasal floor.

[Illustration:

FIG. 94.—HYOID BONE OF OX.

_a_, Body; _b_, lingual process; _c_, thyroid cornu and cartilage, _c′_; _d_, small cornu; _e_, middle cornu; _f_, great cornu; _g_, muscular angle of _f_. (Ellenberger-Baum, Anat. d Haustiere.)]

The two halves of the =mandible= do not fuse completely even in advanced age. The symphyseal surfaces are extremely rough and are marked by reciprocal projections and cavities. The body is shorter, wider, and flatter than in the horse, and has eight round and relatively shallow alveoli for the lower incisors. The interalveolar border is long, curved, thin and sharp. There are no alveoli for the canine teeth, which are absent. The anterior part of the ramus constitutes a long narrow neck. The mental foramen is further forward than in the horse, and is in the posterior end of a fossa. The rami diverge more, so that the submaxillary space is wider than in the horse. They are also more strongly curved, and the angle is more pronounced. The molar part is not so high, especially in its anterior part. Its lower border is convex in its length. Its upper border bears six alveoli for the lower cheek teeth; the first is quite small, and they increase in size from before backward. The vertical part is much smaller than in the horse and its posterior border is relatively thin below, concave and wider above. The mandibular foramen is about in the middle of its inner surface, and a groove for the lingual nerve curves downward and forward from it. The condyle projects inward further than in the horse, and is concave from side to side. The coronoid process is extensive and curves backward.

The =hyoid bone= has a short tuberous lingual process. The middle cornua are almost, as large as the small cornua. The great cornua are narrow, except at the ends. The upper end divides into two branches, which correspond to the two angles of that of the horse. The thyroid cornua do not fuse with the body.

SKULL OF THE OX AS A WHOLE

The skull of the ox is more clearly pyramidal than that of the horse, and is shorter and relatively wider. The cranium is quadrangular and larger externally than in the horse; its large size is due mainly to the great extent of the frontal sinus, and does not affect the cranial cavity, which is smaller than in the horse.

The =superior= or =frontal surface= is formed by the frontals, nasals, and premaxillæ. The frontal part is quadrilateral and very extensive, the greatest width being at the orbits. It presents a central depression on its anterior part, and on either side are the supraorbital grooves and foramina. Behind is the median frontal eminence, and at the lateral angles the “horn-cores” project in horned cattle. The nasal part is very short. The osseous nasal aperture is wide. The premaxillæ do not bend downward as in the horse; they are relatively thin and weak, and are separated by an interval which has a wide anterior part in place of the foramen incisivum.

The =lateral surface= is more triangular than in the horse. The temporal fossa is confined to this surface. It is deep and narrow, and its boundaries are more complete. It is limited above by a crest which extends from the postero-external angle of the frontal to the supraorbital process, and is analogous to the sagittal crest of the horse. Behind it is bounded by the temporal crest. It is clearly marked off from the orbit by the rounded posterior orbital ridge and the pterygoid crest. The zygomatic process is short, weak, and flattened, and is formed by the temporal and malar only. Its condyle is convex and is wide from before backward. The glenoid cavity and postglenoid process are small. The orbit is encroached upon below by the lacrimal bulla, and presents the orifice of the supraorbital canal behind. The margin is completed behind by the frontal process of the malar; its lower part is prominent and rough, not smooth and rounded as in the horse. The pterygo-palatine fossa is much larger, deeper, and more clearly defined. It has a long narrow forward extension (maxillary hiatus) between the vertical plate of the palate bone internally and the maxilla and lacrimal bulla externally; thus the sphenopalatine and maxillary foramina are deeply placed. The preorbital region is short but relatively high. A tuberosity and curved line take the place of the facial crest. The infraorbital foramen is situated above the first cheek tooth and is often double.

The =basal surface= is short and wide, especially in its cranial part. The occipital condyles are limited in front by transverse ridges. The tubercles at the junction of the occipital and sphenoid are large. The condyloid fossæ contain two foramina, the hypoglossal below and in front, and the condyloid above and behind; other inconstant ones occur. The paramastoid processes are short and convergent. The foramen lacerum is slit-like. The bulla ossea is a large, laterally compressed prominence. The muscular processes are usually long and narrow triangular plates, with one or two sharp points. The external auditory process is directed almost straight outward. A curved plate extends downward from it and joins the bulla ossea internally, completing the deep cavity which receives the articular angle of the hyoid bone. The chief external opening of the temporal canal is in front of this plate, and an accessory one lies behind it. The infratemporal fossa is small, and presents the foramen ovale. The posterior nares are very narrow, and the vomer does not reach to the level of their margin. The hard palate is wide, and forms about three-fifths of the entire length of the skull. A small central part only of its posterior border enters into the formation of the posterior nares; the lateral parts are notched and just above them are the posterior palatine foramina. The anterior palatine foramina are an inch or more from the posterior margin, and about the same distance apart. The palatine grooves are distinct for a short distance only. Just beyond the cheek teeth

the palate narrows and becomes concave; beyond this it widens and flattens.

The =posterior= or =nuchal surface= is extensive and somewhat pentagonal in outline in the adult. About its center is the eminence for the attachment of the ligamentum nuchæ. From this a median crest extends toward the foramen magnum, and laterally two lines (Lineæ nuchæ superiores) curve outward, marking the upper limit of the area which is roughened for muscular attachment. The surface above the lines is relatively smooth, and is covered only by the skin and the thin auricular muscles in the living animal. It is separated from the cranial roof by a thick border, which forms centrally the frontal eminence, and bears at its extremities the processus cornu—except in the polled breeds. The condyles are further apart, and the articular surfaces are more clearly divided into upper and lower parts than in the horse.

[Illustration:

FIG. 95.—CROSS-SECTION OF SKULL OF OX. SECTION PASSES THROUGH FIFTH CHEEK TOOTH.]

[Illustration:

FIG. 96.—CROSS-SECTION OF SKULL OF OX. SECTION PASSES THROUGH SECOND CHEEK TOOTH.

_a_, _b_, _c_, Superior, middle, inferior meatus; _b′_, communication between middle meatus and cavity of upper part of inferior turbinal; _c′_, communication between inferior meatus and lower part of inferior turbinal; _d_, cavity of superior turbinal; _e_, _f_, outer and inner walls of _d_; _g_, _h_, upper and lower cavities of inferior turbinal bone; _i_, basal lamella of inferior turbinal; _i′_, _i″_, upper and lower divisions of inferior turbinal bone; _k_, floor of nasal cavity; _m_, lacrimal sinus; _n_, maxillary sinus; _p_, palatine sinus; _q_, septum between maxillary and palatine sinuses; _r_, infraorbital canal; _s_, septum between palatine sinuses; _t_, common meatus; _u_, naso-lacrimal canal; _v_, floor of nasal cavity and roof of palatine sinus; _1_, septum nasi; _2_, posterior part of second cheek tooth; _3_, posterior part of fifth cheek tooth; _4_, hard palate. (After Ellenberger, in Leisering's Atlas.)]

The =cranial cavity= is shorter and its long axis is more oblique than in the horse, but it is relatively high and wide. The anterior fossa lies at a much higher level than the rest of the floor. The olfactory fossæ are smaller, and the sella turcica is much deeper than in the horse. A deep groove leads from the petrous temporal forward over the foramen ovale to the foramen rotundum. Behind the sella there is often a distinct prominence (Dorsum sellæ). The internal sagittal crest is prominent anteriorly, but absent further back. A faintly marked elevation takes the place of the tentorium osseum. The small petrous temporal bone projects into the cavity laterally. The ridges and digital impressions are very pronounced. The parieto-temporal canal is formed entirely in the temporal bone, and opens at the apex of the petrous, where it is joined by the condyloid canal. The foramen lacerum is divided into two parts (For. lacerum anterius et posterius).

The =nasal cavity= is incompletely divided by the septum, which does not reach the floor posteriorly. The floor is relatively long, and is more concave from side to side than in the horse. In the dry skull it has a large oval opening into the palatine sinus, which is closed during life by mucous membrane. The middle meatus is divided behind into upper and lower branches by the great ethmoturbinal. The posterior nares are narrow and oblique.

[Illustration:

FIG. 97.—SKULL OF OX, DORSAL VIEW.

The outer plate of bone has been removed to show the sinuses. _a_, Frontal sinus; _a′_, cranial plate of frontal bone; _a″_, anterior part of frontal sinus, which is separated from remainder by a septum (_b_); _c_, _c′_, communications between frontal sinus and nasal cavity; _d_, supraorbital foramen; _e_, supraorbital canal; _f_, cavity of superior turbinal bone, and _g_, its opening into the nasal cavity; _h_, lacrimal sinus, _i_, its communication with the maxillary sinus; _k_, maxillary sinus; _l_, orbit; _1_, frontal bone; _1′_, processus cornu; _2_, nasal bone; _3_, premaxilla (nasal process); _4_, maxilla; _5_, lacrimal bone; _6_, malar bone; _7_, dotted line indicating course of naso-lacrimal duct. (After Ellenberger, in Leisering's Atlas.)]

The =frontal sinus= is very large. It involves almost all of the frontal bone and a large part of the posterior wall of the cranium. It also extends for a variable distance into the horn processes when these are present. A complete median septum separates the right and left sinuses. The anterior limit is indicated by a transverse plane through the middle of the orbits. It extends externally to the crest which limits the temporal fossa above, and into the root of the supraorbital process. At the highest part of the cranial cavity and at the tuberosity on the posterior surface the two plates of the bone come together. The cavity is very irregular and is subdivided into

numerous spaces by ridges and partial septa. This multilocular character is most marked in the anterior part, and here several small spaces appear to be cut off from the main cavity (Baum). The supraorbital canal passes through the sinus. Several small openings lead from the sinus to the ethmoidal meatuses, and thus indirectly to the upper division of the middle meatus nasi. The communications with the cavity of the superior turbinal and with the lacrimal part of the maxillary sinus which are seen in the macerated skull are closed in the fresh state by mucous membrane.

[Illustration:

FIG. 98.—SKULL OF OX, LATERAL VIEW WITHOUT MANDIBLE.

The maxillary, lacrimal, and turbinal sinuses have been opened, and a portion of the orbit removed, _a_, Cavity of superior turbinal bone; _b_, lacrimal sinus; _c_, maxillary sinus; _d_, communication between maxillary and palatine sinuses; _e_, opening between maxillary and lacrimal sinuses; _f_, thin osseous bulla; _g_, lacrimal bulla; _h_, orbit; _1–6_, cheek teeth; _7_, nasal bone; _8_, premaxilla (nasal process); _9_, maxilla; _9′_, infraorbital foramen; _10_, frontal bone; _11_, lacrimal bone; _12_, malar bone; _13_, fissure between nasal bone and maxilla; _14_, temporal bone (squamous); _15_, external auditory meatus; _16_, styloid or paramastoid process; _17_, occipital condyle; _18_, palate bone (perpendicular part); _19_, pterygoid bone (hamulus); _20_, tympanic part of temporal; _20′_, muscular process of petrous temporal. (After Ellenberger, in Leisering's Atlas.)]

The =maxillary sinus= is excavated chiefly in the maxilla, lacrimal, and malar, and is not divided by a septum as in the horse. It extends forward as far as the facial tuberosity, or a little further in old animals. Its upper limit is indicated approximately by a line drawn from the infraorbital foramen to the upper margin of the orbit. It is continued directly backward into the lacrimal bulla to a point nearly opposite to the bifurcation of the zygomatic process of the malar. It also extends upward and backward through a large opening into a cavity formed by the lacrimal, frontal, ethmoid, and turbinal bones, at the inner side of the orbit.[26] The floor of the cavity is irregular and the roots of the last three or four cheek teeth project up into it, covered by a plate of bone. The sinus communicates with the palatine sinus freely over the infraorbital canal through an oval opening about two to three inches (ca. 5 to 7.5 cm.) long. Above this it communicates by a shorter and much narrower opening with the middle meatus nasi.

The =palatine sinus= is excavated in the hard palate, and is separated from that of the opposite side by a median septum. It extends from the posterior border of the palate to a plane an inch or more (2.5 to 3 cm.) in front of the first cheek tooth. As mentioned above, there is a large communication with the maxillary sinus over the infraorbital canal, so that the cavity is sometimes regarded as a part of that sinus. The large defect in the bony roof of the sinus is closed by two layers of mucous membrane in the fresh state. The palatine canal passes obliquely through the posterior part of the sinus.

The =sphenoidal sinus= is almost entirely in the sphenoid bone and does not communicate with the palatine and maxillary sinus. It has one or two openings into the ventral ethmoidal meatuses. There is no cavity in the perpendicular part of the palate bone.

There are several small air-cavities between the lateral mass of the ethmoid and the anterior part of the frontal sinus, which communicate separately with ethmoidal meatuses.

BONES OF THE THORACIC LIMB

The =scapula= is more regularly triangular than in the horse, relatively wider at the vertebral end and narrower at the lower end. The scapular index is about 1 ■ 0.6. The spine is more prominent and is placed further forward, so that the supraspinous fossa is narrow and does not extend to the lower part of the bone. The spine is sinuous, bent backward in its middle, forward below. Its free border is somewhat thickened in its middle, but bears no distinct tubercle. Instead of subsiding below as in the horse the spine becomes a little more prominent, and is prolonged by a pointed projection, the =acromion=, from which part of the deltoid muscle arises. The subscapular fossa is shallow. The areas for the attachment of the serratus muscle are not very distinct. The nutrient foramen is usually in the lower third of the posterior border. The glenoid cavity is almost circular and without any distinct notch. The tuberosity is small and close to the glenoid cavity. The coracoid process is short and rounded. The cartilage resembles that of the horse.

The =humerus= has a shallow musculo-spiral groove. The deltoid tuberosity is less prominent than in the horse, and the curved line running from it to the neck bears a well-marked tubercle on its upper part. The nutrient foramen is usually in the lower third of the posterior surface. The external tuberosity is very large, and rises an inch or more (ca. 3 cm.) above the level of the head. Its anterior part curves inward over the bicipital groove, and below it externally there is a prominent circular rough area for the insertion of the tendon of the supraspinatus. The anterior part of the internal tuberosity has a small projection which curves over the groove.

The groove is undivided. The distal articular surface is decidedly oblique, and the grooves and ridge are very well marked. The coronoid and olecranon fossæ are deep and wide. The external condyloid crest is represented by a rough raised area. The proximal end unites with the shaft at three and one-half to four years, and the distal at about one and one-half years.

The =radius= is short and relatively broad. It is somewhat oblique, the lower end being nearer the median plane than the upper. The curvature is more pronounced below than above. The shaft is prismatic in its middle part and has anterior, external, and posterior faces. There is a marked increase in width and thickness below. The proximal articular surface presents a synovial fossa which extends inward from the deep groove between the two glenoid cavities. The bicipital tuberosity is represented by a slightly elevated rough area. The posterior facets for the ulna are larger than in the horse. The two bones commonly fuse above the proximal interosseous space and always fuse below it, except near the distal end, where there is a small distal interosseous space. A groove connects the two spaces externally. The distal extremity is large, and is thickest internally. Its articular surface is oblique in two directions, _i. e._, from within upward and backward. The grooves for the extensor tendons are shallow. The proximal end unites with the shaft at one to one and one-half years, and the distal at three and one-half to four years.

The approximation of the lower ends of the forearms and the carpi gives the “knock-kneed” appearance in cattle. The obliquity of the joint surfaces produces lateral deviation of the lower part of the limb in flexion. The facets for the radial and intermediate carpals are narrower than in the horse and run obliquely forward and outward. The surface for the ulnar carpal is extensive and saddle-shaped; its outer part is furnished by the ulna.

[Illustration:

FIG. 99.—SKELETON OF LEFT FORE LIMB OF OX, FROM SHOULDER DOWNWARD, ANTERIOR VIEW. (After Ellenberger-Baum, Anat. für Künstler.)]

The =ulna= is more fully developed than in the horse. The shaft is complete, three-sided, and strongly curved. It is fused with the radius in the adult, except at the two interosseous spaces mentioned above. Its upper part contains a medullary canal which extends somewhat into the proximal end. The olecranon is large and bears a rounded tuberosity above. The distal end is fused with the radius; it projects below the level of the latter, forming the =styloid process= (Processus styloideus ulnæ), which furnishes part of the facet for the ulnar carpal. The proximal and distal ends unite with the shaft at three and one-half to four years.

[Illustration:

FIG. 100.—SKELETON OF LEFT FORE LIMB OF OX, FROM ELBOW DOWNWARD, EXTERNAL VIEW. (After Ellenberger-Baum, Anat. für Künstler.)]

The =carpus= consists of six bones, four in the upper row, and two in the lower. The upper row is oblique in conformity with the carpal articular surface of the radius. The radial and intermediate resemble in general those of the horse, but are less regular in shape, and their long axes are directed obliquely backward and inward. The radial is narrower than in the horse and curves upward behind. The intermediate is constricted in its middle, and wider behind than in front. The ulnar is large and very irregular. Its proximal surface is extensive and sinuous and articulates with both radius and ulna. Behind is a large oval facet for articulation with the accessory carpal. The accessory is short, thick, and rounded; it articulates with the ulnar carpal only. The first carpal is absent. The second and third carpals are fused to form a large quadrilateral bone. The fourth carpal is a smaller quadrilateral bone.

The =metacarpus= consists of a large metacarpal and an external small metacarpal bone. The large metacarpal bone (Mc. 3 + 4) results from the fusion of the third and fourth bones of the fœtus, and bears evidences of its double origin even in the adult state. The shaft is shorter than in the horse, and is relatively wider and flatter. The anterior surface is rounded, and is marked by a vertical vascular groove connecting two canals which traverse the ends of the shaft from before backward. The posterior surface is flat and presents a similar but much fainter groove. The borders are rough in the upper third. The proximal end bears two slightly concave facets for articulation with the bones of the lower row of the carpus; the inner area is the larger, and they are separated by a ridge in front and a notch behind. The outer angle has a facet behind for the small metacarpal bone. The inner part of the extremity has anterior and posterior tuberosities. The distal end is divided into two parts by a sagittal notch. Each division bears an articular surface similar to that in the horse, but much smaller. The =medullary canal= is divided into two parts by a =vertical septum= which is usually incomplete in the adult.

The =small metacarpal= bone (Mc. 5) is a rounded rod about an inch and a half (ca. 3.5 to 4 cm.) in length, which lies against the upper part of the outer border of the large bone. Its upper end articulates with the latter, but not with the carpus. The lower end is pointed.

Four cartilaginous metacarpals are present in the early fœtal state, viz., the second, third, fourth, and fifth. The second commonly either disappears or unites with the third; sometimes it develops as a small rod of bone. The third and fourth gradually unite, but can be cut apart at birth. Each has three centers of ossification; the proximal epiphysis fuses with the shaft before birth, the distal at two to two and one-half years.

Four =digits= are present in the ox. Of these, two—the third and fourth—are fully developed and have three phalanges and three sesamoids each. The second and fifth are vestiges and are placed behind the fetlock; each contains one or two small bones which do not articulate with the rest of the skeleton.

The =first phalanges= are shorter and narrower than in the horse and are three-sided. The interdigital surface is flattened and its posterior part bears a prominence for the attachment of the interdigital ligaments. The proximal extremity is relatively large, and is somewhat compressed from side to side. The articular surface is concave from before backward and is divided by a sagittal groove into two areas, of which the abaxial one is the larger and higher. Behind these are two facets for articulation with the sesamoid bones. The posterior surface bears two tuberosities separated by a deep depression. The distal extremity is smaller than the proximal, especially in the antero-posterior direction. Its articular surface is divided by a sagittal groove into two convex facets, of which the abaxial one is decidedly the larger. There are depressions on either side for ligamentous attachment. The bone consists at birth of two pieces—the distal end and the fused shaft and upper extremity. Union occurs at one and one-half to two years.

The =second phalanges= are about two-thirds of the length of the first and are distinctly three-sided. The proximal articular surface is divided by a sagittal ridge into two glenoid cavities, of which the abaxial one is much the larger. There is a central prominence in front and two lateral tubercles behind. The distal extremity is smaller than the proximal. Its articular surface encroaches considerably on the anterior and posterior surfaces, and is divided into two lateral parts by a groove. There is a deep depression for ligamentous attachment on the interdigital side. The bone contains a small medullary canal. The distal end unites with the rest of the bone about the middle of the second year.

The =third phalanges= resemble in a general way one-half of the bone of the horse. Each has four surfaces. The dorsal or wall surface is marked in its lower part by a shallow groove, along which there are several foramina of considerable size; the posterior one of the series is the largest, and conducts to a canal in the interior of the bone. Below the groove the surface is prominent, rough, and porous. Near and on the extensor process are several relatively large foramina. The slope of the surface is very steep posteriorly, but in front it forms an angle of 25 to 30 degrees with the ground plane. The articular surface is narrow from side to side, and slopes downward and backward. It is also oblique transversely, the interdigital side being the lower. It is adapted to the distal surface of the second phalanx, with the exception of a facet behind for the distal sesamoid. The extensor process is very rough. The volar or sole surface is narrow and slightly concave, and presents two or three foramina of considerable size. It is separated from the wall surface by a border which is sharp in front, rounded behind. There is no semilunar crest, since the deep flexor tendon is attached to the thick posterior border of the sole surface. The interdigital surface is smooth and grooved below, rough and porous above. At the upper angle it is perforated by a large foramen, which is equivalent to the volar foramen of the horse and leads to a cavity in the middle of the bone. The surface is separated by a rounded border from the wall surface, and by a sharp edge from the sole surface. The wing or angle is very short and blunt, and there is no lateral cartilage.

Four =proximal sesamoids= are present, two for each digit. They are much smaller than in the horse. The bones of each pair articulate with the corresponding part of the distal end of the large metacarpal bone by their anterior surfaces, with each other and with the first phalanx by small facets.

The two =distal sesamoids= are short and their ends are but little narrower than the middle.

BONES OF THE PELVIC LIMB

The =ilia= are almost parallel to each other and are also less oblique with regard to the horizontal plane than in the horse. They are relatively small. The gluteal line is prominent and is nearly parallel to the external border; it joins the superior ischiatic spine. A rounded ridge separates the two parts of the ventral surface. The surface for articulation with the sacrum is triangular. The internal angle is truncated, does not extend as high as the vertebral spines, and is separated from the opposite angle by a wider interval

than in the horse. The external angle is relatively large and prominent; it is not so oblique as in the horse, and is wide in the middle, smaller at either end. The shaft is short and compressed from side to side.

The =ischium= is large. Its long axis is directed obliquely upward and backward, forming an angle of about 45 to 50 degrees with the horizontal plane. The transverse axis is oblique downward and inward at a similar angle, so that this part of the pelvic floor is deeply concave from side to side. The middle of the ventral surface bears a rough ridge or imprint for muscular attachment. The superior ischiatic spine is high and thin, and bears a series of almost vertical rough lines externally. The tuber ischii is large and three-sided, bearing upper, lower, and external tuberosities. The ischial arch is narrow and deep. The symphysis bears a ventral ridge, which fades out near the ischial arch.

The acetabular branch of the =pubis= is narrow, and is directed outward and a little forward. The anterior border is marked by a transverse groove which ends below the rough ilio-pectineal eminence. The longitudinal branch is wide and thin.

The =acetabulum= is smaller than in the horse. The rim is rounded and is usually marked by two notches. One of these is postero-internal and is narrow and deep; it leads to the deep acetabular fossa and is commonly almost converted into a foramen by a bar of bone. The other notch is antero-internal, small, and sometimes replaced by a foramen or absent.

The =obturator foramen= is large and elliptical. Its inner border is thin and sharp.

[Illustration:

FIG. 101.—SKELETON OF LEFT HIND LIMB OF OX, FROM MIDDLE OF THIGH DOWNWARD, POSTERIOR VIEW. _21_, Tibia; _24_, tuber calcis; _25_, large metatarsal bone. (After Ellenberger-Baum, Anat. für Künstler.)]

The =pelvic inlet= is elliptical and is more oblique than in the horse. In a cow of medium size the =conjugate diameter= is about nine and a half inches (ca. 23 to 24 cm.), and the transverse about seven inches (ca. 18 cm.). The anterior end of the symphysis lies in a transverse plane through the junction of the third and fourth sacral segments. The roof is concave in both directions. The =floor= is deeply concave, particularly in the transverse direction. The =cavity= is narrower and its =axis= is inclined strongly upward in the posterior part. The distance between the acetabulum and the external angle of the ilium is only a little (ca. 3 to 4 cm.) more than the distance between the former and the tuber ischii.

[Illustration:

FIG. 102.—FRONTAL SECTION OF LEFT FEMUR OF OX, FRONT VIEW.]

[Illustration:

FIG. 103.—FRONTAL SECTION OF LEFT TIBIA OF OX, ANTERIOR VIEW.

These figures show the internal architecture of these bones, and especially the great extent of the medullary cavity as compared with those of the horse (Figs. 67 and 72).]

The =femur= has a relatively small shaft, which is cylindrical in its middle, prismatic below. The trochanter minor has the form of a rough tuberosity, and is situated higher up than in the horse and encroaches on the posterior surface. The trochanteric ridge (Crista intertrochanterica posterior) connects it with the trochanter major. The third trochanter is absent. The supracondyloid (plantar) fossa is shallow. The proximal extremity is very wide. The head is smaller than in the horse and the articular surface extends considerably on the upper surface of the neck. Instead of the notch there is a small depression on the middle of the head for the attachment of the round ligament. The neck is well defined except above. The trochanter major is very massive and is undivided; its external surface is very rough. The trochanteric fossa is deep, but does not extend so far downward as in the horse. The distal end presents no very striking differential features, but the lips of the trochlea are less oblique than in the horse, and converge very slightly below. The proximal extremity unites with the shaft at about three and one-half years, the distal at three and one-half to four years.

The =tibia= resembles that of the horse rather closely, but is somewhat shorter. The shaft is distinctly curved, so that the inner side is convex. The posterior surface is not divided into two areas, and the lineæ musculares are fewer and extend up higher than in the horse. The articular grooves and ridge of the distal end are almost sagittal in direction, and present an extensive but shallow synovial fossa. The external groove is separated by a sharp ridge from an outer area which is for articulation with the external malleolus. The anterior part of the internal malleolus is prolonged downward and has a pointed end. The groove behind it is broad

and well defined. Externally there is a deep narrow groove which separates two prominences. The proximal extremity fuses with the shaft at three and one-half to four years, the distal at two to two and one-half years.

The =fibula= usually consists of the two extremities only. The head is fused with the external condyle of the tibia and bears a small blunt-pointed prolongation below. The distal end remains separate and forms the external malleolus (sometimes called the os malleolare). It is quadrilateral in outline and compressed from side to side. The proximal surface articulates with the distal end of the tibia, and bears a small spine which fits into the groove on that bone. The distal surface rests on the fibular tarsal, and the inner articulates with the external ridge of the tibial tarsal bone. The outer surface is rough and irregular.

The early cartilaginous fibula is complete, but later the shaft is reduced and is usually represented by a fibrous cord which connects the two ends. In some cases, however, the upper part undergoes partial ossification, forming a slender rod which is usually united with the outer border of the tibia and is joined to the head by fibrous tissue.

The =patella= is long, narrow, and very thick. The anterior surface is strongly convex and very rough and irregular. The articular surface is convex from side to side and nearly straight in the vertical direction. The large prominence on the inner side for the attachment of the accessory cartilage allows prompt determination of the side to which the bone belongs. The apex is more pointed than in the horse.

The =tarsus= consists of five pieces; the central and fourth, and the second and third tarsal bones are fused.

The =tibial tarsal= bone is relatively long and narrow, and is somewhat flattened from before backward. It bears a trochlea at either end. The groove and ridges of the proximal trochlea are not spiral, but almost sagittal; the outer ridge is the wider, and articulates with both tibia and fibula. The distal trochlea consists of two condyles divided by a groove, and articulates with the combined central and fourth tarsals. The posterior surface bears a large oval facet for articulation with the fibular tarsal; this occupies most of the surface, and is convex and grooved from above downward. The outer surface presents two facets for articulation with the fibular tarsal, and is excavated and rough elsewhere. The inner surface bears a tuberosity at its upper part, and is flattened below.

The =fibular tarsal= bone is longer and more slender than in the horse. The distal part of the body is compressed laterally, and bears a projection in front which articulates with the external malleolus. The tuber calcis is marked posteriorly by a wide shallow groove, which is coated with cartilage in the fresh state.

The =central= and =fourth tarsals= are fused to form a large bone (Os centrotarsale quartum, scapho-cuboid), which extends across the entire width of the tarsus and articulates with all of the other bones. The greater part of the upper surface is molded on the distal trochlea of the tibial tarsal, and its inner part rises high above the rest posteriorly. Externally there is a narrow undulating surface for articulation with the distal end of the fibular tarsal bone. The posterior surface bears two tuberosities, of which the outer one is rounded, the inner more prominent and narrower.

The =first tarsal= bone is quadrilateral and small. It articulates with the central above, the metatarsus below, and the second tarsal in front.

The =second= and =third tarsals= are fused to form a rhomboid piece. The proximal surface is concavo-convex, and articulates with the central component. The distal surface is undulating and rests on the metatarsus. The external surface bears a small facet in front for the fourth tarsal component, and the posterior surface a very small one for the first tarsal bone.

The =large metatarsal= bone is about one-seventh (ca. 3 cm.) longer than the corresponding metacarpal. Its shaft is compressed laterally and is distinctly four-sided. The groove on the anterior surface is deep and wide. The posterior surface is marked by variable grooves. The upper foramen on this surface does not perforate the shaft, but passes obliquely through the extremity, opening on the posterior part of its proximal surface. The postero-internal angle of the proximal end bears a facet for articulation with the small metatarsal bone.

[Illustration:

FIG. 104.—SKELETON OF DISTAL PART OF LEFT HIND LIMB OF OX, INTERNAL VIEW. _24_, Tuber calcis; _25_, large metatarsal bone; _30_, first phalanx; _31_, second phalanx; _32_, third phalanx. (After Ellenberger-Baum, Anat. für Künstler.)]

The =small metatarsal= bone is a quadrilateral disc a little less than an inch in width and height. Its anterior face bears a facet for articulation with the large metatarsal bone.

The large metatarsal bone is usually regarded as consisting of the fused third and fourth metatarsal bones. The medullary cavity is subdivided like that of the large metacarpal bone. Some anatomists, however, consider that the ridges at the upper end of each border represent the second and fifth metatarsals (Rosenberg and Retterer). On this basis the small bone would be the first metatarsal.

The =phalanges= and =sesamoids= resemble those of the thoracic limb so closely as to render separate description unnecessary.

SKELETON OF THE PIG

VERTEBRAL COLUMN

The =vertebral formula= is C_{7}T_{14–15}L_{6–7}S_{4}Cy_{20–23}.

[Illustration:

FIG. 105.—SKELETON OF PIG, LATERAL VIEW.

(After Ellenberger, in Leisering's Atlas.)]

The =cervical vertebræ= are short and wide. The bodies are elliptical in cross-section, the long diameter being transverse. The anterior articular surfaces are slightly convex from side to side and concave dorso-ventrally; the posterior ones are slightly concave. A ventral crest is not present. The arches are wide from side to side, but the laminæ are narrow, so that a considerable interval (Spatium interarcuale) separates adjacent arches dorsally. The pedicles are perforated by a foramen on either side in addition to the usual intervertebral foramina. The transverse processes divide into two branches, both of which increase in size from the third to the sixth. The upper branch projects outward and backward; it is short and is thickened at its free end. The lower branch is a quadrilateral plate directed ventrally; each overlaps the succeeding one to a small extent, and the series forms the lateral boundary of a deep and wide groove beneath the bodies. The spines increase in height from the third to the last; the anterior ones are inclined backward, the posterior ones forward. The last cervical is recognized by the great length of its spine (ca. 10 cm. in the adult), the absence of the ventral plate of the transverse process, and the flatness of the body, which bears a pair of small facets on its posterior margin for the heads of the first ribs. It has foramina transversaria, and usually two foramina in either side of the arch.

The dorsal arch of the =atlas= bears a large tuberosity. The ventral tubercle is long, compressed laterally, and projects back under the axis. The wing is flattened and bears a posterior tuberosity. The foramen transversarium passes through the posterior border of the wing to the fossa under the latter, and is not visible dorsally; it is sometimes very small or absent. The sides of the vertebral foramen bear two lateral projections which partially divide it into a ventral narrow part, which receives the odontoid process, and a dorsal larger part for the spinal cord. In the fresh state the division is completed by the transverse ligament, which is attached to the projections.

The =axis= has a large spinous process, which is directed upward and backward. The odontoid process is a thick cylindrical rod. The transverse process is very small and the foramen transversarium is often incomplete.

[Illustration:

FIG. 106.—ATLAS OF PIG, DORSAL VIEW.

_a_, Wing; _b_, ventral tubercle; _c_, foramen transversarium; _d_, alar foramen; _e_, intervertebral foramen; _f_, dorsal tuberosity; _g_, articular surface corresponding to that of posterior articular process of typical vertebra; _h_, facet on ventral arch

for odontoid process. (Ellenberger-Baum, Anat. d. Haustiere.)]

[Illustration:

FIG. 107.—AXIS OF PIG, LEFT LATERAL VIEW.

_a_, Odontoid process (dens); _b_, spinous process; _c_, anterior articular process; _d_, posterior articular processes; _e_, transverse process; _f_, foramen transversarium; _g_, bar of bone which bounds _h_, intervertebral foramen; _i_, vertebral foramen. (Ellenberger-Baum, Anat. d. Haustiere.)]

The =thoracic vertebræ= are often fifteen in number. Their bodies are relatively long, constricted in the middle, and without ventral crests. Their extremities are elliptical, depressed in the middle and prominent at the periphery. The arch is perforated by a foramen on either side, and in most of the series there is also a foramen in the posterior part of the root of the transverse process which communicates with the former or with the posterior intervertebral foramen. Sometimes there is a foramen in the anterior part of the process also. There are mammillary processes except on the first two; in the posterior five or six vertebræ they project from the anterior articular processes. The facet for the tubercle of the rib is absent or fused with that for the head in the last five or six. The last transverse process is lumbar in character, plate-like, and about an inch (2 cm.) long. Small accessory processes occur in the posterior part of the region. The first spinous process is broad, very high, and inclined a little forward. The others diminish very gradually in length to the tenth, beyond which they are about equal. The second to the ninth are inclined backward, the tenth is vertical (anticlinal), and the rest incline forward. The width decreases decidedly from the fourth to the tenth, beyond which there is a gradual increase. The summits are slightly enlarged and lie almost in a straight line.

The occurrence of fifteen thoracic vertebræ appears to be quite common, and some observers have recorded the existence of sixteen and even seventeen; a reduction to thirteen is rare.

The =lumbar vertebræ= are six or seven in number. The bodies are longer than in the thoracic region and bear a ventral crest. They become wider and flatter in the posterior part of the series. The arches are deeply notched, and are separated by an increasing space dorsally. The mammillary processes project outward and backward. The transverse processes are bent downward and incline a little forward. Their length increases to the fifth and is much diminished in the last. They form no articulation with each other or with the sacrum. The posterior edge of the root of the process is marked by a notch in the anterior part of the series, a foramen in the posterior part. The spines are broad and incline forward, with the exception of the last, which is narrow and vertical.

Lesbre states that six and seven lumbar vertebræ occur with almost equal frequency. The number may be reduced to five, and the number of presacral vertebræ varies from twenty-six to twenty-nine.

The =sacrum= consists usually of four vertebræ, which fuse later and less completely than in the other domesticated animals. It is less curved than in the ox. The spines are absent, excepting small rudiments on the last two segments. The middle of the dorsal surface is flattened and smooth, and presents openings into the sacral canal between adjacent arches (Spatia interarcualia). On either side are the superior sacral foramina, and tubercles which indicate the fused articular processes. The wings resemble those of the ox. The anterior articular processes are very large. The pelvic surface resembles that of the ox, but is not so strongly curved, and the transverse lines are very distinct.

[Illustration:

FIG. 108.—SACRUM OF PIG, DORSAL VIEW.

_a_, Wing; _b_, dorsal sacral foramina; _c_, articular process; _1–4_, segments or sacral vertebræ. (Ellenberger-Baum, Anat. d. Haustiere.)]

The =coccygeal vertebræ= are specially characterized by the presence of functional articular processes on the first four or five, beyond which these processes become non-articular and smaller. The arches of the first five or six are complete. The transverse processes are broad and plate-like in the anterior part of the series and diminish very gradually.

The numerical variation here is twenty to twenty-six according to the observation of several anatomists. Lesbre states that he has found twenty-three most frequently.

=Curves.=—The cervical region is practically straight. The thoracic and lumbar regions form a gentle curve, concave ventrally, the highest point of which is at the junction of the two regions. The sacral promontory is not so pronounced as in the ox, and the sacral curve is flatter.

THE RIBS

The =ribs= number fourteen or fifteen pairs, of which seven are sternal and seven or eight asternal usually. They are in general strongly curved in the improved breeds, so that there is a fairly distinct angle, except toward the end of the series. The backward slope of the posterior ribs is slight. The first rib is prismatic, has a large sternal end, and a very short cartilage. The width is greatest in the third to the sixth, and the length in the sixth and seventh usually. The tuberosity fuses with the head on the last five or six. The second to the fifth form diarthrodial joints with their cartilages, which are wide and plate-like.

THE STERNUM

The =sternum= consists of six segments and resembles that of the ox in general form. The first segment (Manubrium) is long, flattened laterally, and bears a blunt-pointed cartilage on its anterior end; its posterior end forms a diarthrodial joint with the body. The latter is flattened, wide in its middle, narrow at either end. The widest segments are formed of two lateral parts, which are not completely fused in the adult. The last segment has a long narrow part which bears the xiphoid cartilage.

The =thorax= is long and is more barrel-shaped than in the horse or ox, since the ribs are more strongly curved and differ less in relative length.

[Illustration:

FIG. 109.—SKULL OF PIG, LATERAL VIEW WITHOUT MANDIBLE.

BONES OF THE SKULL

CRANIUM

The =occipital bone= has an extensive squamous part or supraoccipital, which forms a very broad and prominent crest. The latter is concave, and is thick and rough above, where it forms the highest part of the skull; laterally it becomes thinner, turns downward, and is continuous with the temporal crest. Two divergent ridges pass upward from the foramen magnum, and the surface between them is concave and smooth. The greater part of the inner (or anterior) surface of the supraoccipital is united with the parietal bones, but a lower concave area faces into the cranial cavity. The foramen magnum is almost triangular, and is narrow above, where it is flanked by two small tuberosities. The paramastoid processes are extremely long and project almost straight downward. The hypoglossal foramen is at the inner side of the root of the process. The basilar part is short and wide; its lower surface bears a thin median ridge and two lateral imprints or tubercles which converge at the junction with the sphenoid bone.

[Illustration:

FIG. 110.—SKULL OF PIG, DORSAL VIEW.]

The =interparietal= fuses before birth with the occipital. The tentorium osseum is absent.

The =parietal= is overlapped by the occipital bone behind and concurs in the formation of the occipital crest. Its external surface is divided by the parietal crest into two parts. The inner part (Planum parietale) faces upward and forward, and is flattened and smooth. Its inner border is short and straight and unites early with the opposite bone. Its anterior border is concave and joins the frontal bone. The outer part (Planum temporale) faces outward and is more extensive; it is concave, forms a large part of the temporal fossa, and is overlapped below by the squamous temporal. The parietal crest extends in a curve from the occipital crest forward and outward to the supraorbital process. The internal surface is concave and is marked by digital impressions. The lower border projects into the cranial cavity and forms a crest which separates the cerebral and cerebellar compartments laterally. The

interior forms part of the frontal sinus in the adult. There is no parieto-temporal canal.

The =frontal bone= is long. The frontal surface slopes downward and forward, the inclination varying in different subjects. The anterior part is concave and is marked by the supraorbital foramen and the groove leading forward from the foramen to the nasal bone. The supraorbital canal opens into the orbit at the upper part of the inner wall of the latter. The supraorbital process is short and blunt-pointed, and is not connected with the zygomatic arch. The gap in the orbital margin is closed by the orbital ligament in the fresh state. The orbital part is extensive and forms the greater part of the inner wall of the orbit. Its upper part is perforated by the orbital orifice of the supraorbital canal, in front of which is the distinct fovea trochlearis. The ethmoidal or internal orbital foramen is situated in the lower part near the junction with the orbital wing of the sphenoid. The temporal part is very narrow and is separated from the orbital plate by a ridge which joins the pterygoid crest below. The interior of the bone is excavated by the frontal sinus in practically its entire extent in the adult. In the young subject the cavity is confined to the anterior part and the rest of the bone is thick.

The =temporal bone= has a general resemblance to that of the ox. The zygomatic process is short and stout and is bent at a right angle. The upper border of the process is thin; traced from before backward it curves sharply upward and forms a high prominence in front of the external auditory meatus; beyond this it drops rather abruptly and is then continued upward to the occipital crest. The anterior part of the lower border joins the zygomatic process of the malar, which is deeply notched. The condyle is concave in the transverse direction. The postglenoid process is absent, but the articular surface is bounded behind and internally by a crest. There is no parieto-temporal canal. The external auditory canal is very long and is directed upward and outward. The bulla ossea is large, compressed laterally, and bears a pointed muscular process in front. A narrow space intervenes between the bulla and the basilar part of the occipital bone, so that the foramen lacerum resembles that of the horse. The small hyoid process is situated in a deep depression in front of the root of the paramastoid process, and the stylo-mastoid foramen is immediately external to it. The petrous part presents no important differential features. The squamous part (including the root of the zygomatic process) contains an air-cavity, which is continuous with the sphenoidal sinus.

[Illustration:

FIG. 111.—BASAL SURFACE OF SKULL OF YOUNG PIG, WITHOUT THE MANDIBLE.

_Sq.o._, Supraoccipital; _E.o._, exoccipital; _B.o._, basioccipital; _B.s._, body of sphenoid; _Sq._, squamous temporal bone; _V_, vomer; _Mx._, maxilla; _Pa._, horizontal part of palate bone; _P.p._, palate process of maxilla; _Z_, malar bone; _J_, premaxilla; _D.c._, canine tooth; _J1–3_, incisor teeth; _O_, temporal fossa; _1_, occipital crest; _2_, for. magnum; _3_, occipital condyle; _4_, paramastoid (styloid) process; _5_, bulla ossea; _6_, for. lacerum basis cranii; _7_, pterygoid process of sphenoid; _8_, posterior nares; _9_, anterior palatine foramen; _10_, palatine cleft. (Struska, Anat. d. Haustiere.)]

The =sphenoid bone= is short and resembles that of the ox in general. The body is narrow. The pituitary fossa is very deep, and is limited behind by a prominent dorsum sellæ; the dorsum bears lateral projections, the =posterior clinoid processes=. The foramen ovale is absent, being included in the foramen lacerum anterius. The other foramina are like those of the ox. The pterygoid process is broad and twisted. Its base is not perforated and its free edge is thin and sharp. It concurs with the pterygoid and palate bones in the formation of the pterygoid fossa, which opens backward and is not present in the horse or ox. The sphenoidal sinus is very large and occupies the body, the temporal wings, and a great part of the pterygoid processes in the adult; it is continued into the temporal bone as mentioned above.

The =ethmoid bone= has a relatively long perpendicular plate, which is marked by ridges corresponding to the ethmoidal meatuses. The cribriform plate is extensive and very oblique, so that it and the crista galli are almost in line with the basi-cranial axis. A linear series of relatively large foramina is found on either side of the crista. The lateral mass consists of five endoturbinals and eighteen ectoturbinals (Paulli). The lamina papyracea concurs in the formation of the pterygo-palatine fossa.

FACE

The =maxilla= is extensive. Its external surface forms a longitudinal groove, which is continued upon the premaxilla in front and the facial parts of the lacrimal and malar behind. The infraorbital foramen—sometimes double—is large and is situated above the third or fourth cheek tooth. The alveolus for the canine tooth produces a ridge at the anterior end which is very pronounced in the boar. The facial crest extends forward from the root of the zygomatic process and fades out behind the infraorbital foramen; in some specimens it is prominent and thin-edged, in others it is rounded and projects little. The zygomatic process is short but stout and

buttress-like; it is overlapped externally by the malar. The maxillary tuberosity forms in the young subject a long bulla, which occupies most of the pterygo-palatine fossa and contains the developing permanent molars; after the eruption of the teeth the tuberosity flattens and joins the vertical part of the palate bone. The palatine process is very long and is marked in its anterior part by transverse ridges corresponding with those of the mucous membrane of the palate. The anterior palatine foramen is near the junction with the palate bone; from it the palatine groove can be traced distinctly along the entire length of the process. The alveolar border presents a large alveolus for the canine tooth at its anterior end; behind this are seven alveoli for the cheek teeth, which increase in size from first to last. The maxillary foramen and infraorbital canal are very large. The maxillary sinus is small.

The body of the =premaxilla= is narrow and prismatic. It presents three alveoli for the incisor teeth, which are separated by short intervals and diminish in size from before backward. As in the ox, a narrow space separates the right and left bones and takes the place of the foramen incisivum. The palatine process is long and narrow. The nasal process is very extensive and is somewhat rhomboid in outline. Its upper border forms a very long suture with the nasal bone, and the lower articulates to about the same extent with the maxilla. The palatine fissure is relatively wide.

The horizontal part of the =palate bone= forms a fourth to a fifth of the length of the palate; its palatine surface is triangular, the apex being anterior; its nasal surface is deeply grooved and smooth. A pterygoid process (processus pyramidalis of man) projects backward and downward, and its thick rounded end is received between the pterygoid process of the sphenoid and the pterygoid bone. The perpendicular part is largely overlapped externally by the maxilla and concurs in forming part of the palatine canal. Superiorly the two plates separate and inclose an air-cavity which opens into an ethmoidal meatus. The inner plate curves inward and unites with the vomer and ethmoid to form a horizontal plate (Lamina transversalis), which divides the posterior part of the nasal cavity into an upper olfactory part and a lower respiratory part.

The =pterygoid bone= is nearly vertical in direction, and is narrow in its middle, wide at each end. The external surface is free below and forms the inner wall of the pterygoid fossa. The lower end is notched and forms a distinct hamulus.

The =nasal bone= is very long and its width is almost uniform, except at the anterior end, which is pointed and reaches almost as far forward as the premaxilla. The facial surface is flattened from side to side. In profile it is nearly straight in some subjects, variably concave in others. The external border is free to a small extent in front only; otherwise it is firmly connected with the premaxilla and maxilla. In the adult the frontal sinus extends into the posterior part of the bone.

The =lacrimal bone= is very sharply bent. Its facial surface presents a deep depression, surmounted by a ridge or tubercle. On or close to the orbital margin are two lacrimal foramina which lead to the lacrimal canals. The orbital surface presents a fossa in which the inferior oblique muscle of the eyeball arises, and its lower part bears a crest, which is crossed obliquely by a vascular furrow. The upper border articulates with the frontal only. The bone concurs in the formation of the maxillary sinus.

The =malar bone= is strongly compressed from side to side. Its facial surface is small and presents a fossa which is continuous with the depressions of the maxilla and lacrimal. The orbital surface is still smaller and is smooth and deeply grooved. The zygomatic process is very extensive, especially in the vertical direction. Its external surface is convex and free, and bears a rough eminence in its middle. Its internal surface is concave; it is overlapped in front by the maxilla, and in the remainder of its extent is free and smooth. The upper border is thick and rounded in front, where it forms the lower part of the orbital margin; behind this it forms an extensive notch which receives the zygomatic process of the temporal. (It might be regarded as dividing into frontal and temporal branches.) The lower border is convex and becomes thinner behind.

The =turbinal bones= resemble those of the ox. The superior turbinal is, however, relatively longer, less fragile, and more firmly attached to the nasal bone. There is no middle turbinal.

The =vomer= is very long. The anterior extremity reaches to the body of the premaxilla or very close to it. The lower border is received into a groove formed by the nasal crest of the maxillæ and palate bones and in front by the palatine processes of the premaxillæ. The posterior border is concave, thin, and sharp.

The =os rostri= (or prenasal bone) is situated in the snout between the nostrils. It has the form of a short three-sided prism. The upper surface is convex and is notched at each end. The lateral surfaces are concave, smooth, and converge below, forming a grooved lower border. The posterior surface is triangular, notched centrally, and rough laterally. The anterior surface is deeply pitted and is surrounded by an irregular sharp border.

The =mandible= is very strong, and differs very much from that of the horse or ox. The body narrows decidedly in front; the lingual surface is deeply concave; the mental surface is strongly convex, slopes downward and backward, and forms a distinct prominence at the point of divergence of the rami. Above this prominence is a pair of foramina. The alveolar border presents six alveoli for the incisor teeth, and a little further back two large cavities for the canine teeth. There are two pairs of mental foramina of considerable size and a variable number of smaller ones. The rami diverge more than in the horse or ox, and the upper part is somewhat incurved. The horizontal part is very thick and strong. Its outer surface is strongly convex from above downward. The inner surface is prominent over the roots of the molar teeth and overhangs the concave lower part. The alveolar border is thin in front and widens behind; it does not follow the axis of the ramus, but runs nearly straight and produces the marked overhang noted above. There are seven alveoli for the lower cheek teeth, which increase in size from before backward. The first is small, not always present in the adult, and is separated by short spaces from the second and the canine alveolus. The vertical part is relatively wide above. The condyle is convex in both directions, wide in front, narrow and declivitous behind. The very small and thin-edged coronoid process is not quite so high as the condyle, from which it is separated by a very wide notch. The mandibular foramen is large. The two halves of the bone unite soon after birth in the improved breeds.

The body of the =hyoid bone= is broad from before backward, short transversely, and bears on its ventral aspect a very short pointed lingual process. The thyroid cornua are wide and curved, concave and grooved dorsally; their ends are attached to the thyroid cartilage of the larynx by rather long bars of cartilage. The small cornua are short, wide, and flattened dorso-ventrally; they are attached to short bars which project from the junction of the body and thyroid cornua. The middle cornu is a little longer than the small cornu, but is relatively slender; it is largely cartilaginous in the young subject and does not ossify at either end. The great cornu is a very slender rod, slightly enlarged at either end; the upper extremity is attached to the hyoid process of the temporal by a rather long and wide bar of cartilage.

FIG. 112.—MANDIBLE OF PIG.

_a_, Body of mandible; _b_, horizontal part of ramus; _f_, vertical part of ramus; _c_, interalveolar border; _c′_, interval between canine and corner incisor; _c″_, interval between first and second premolars; _d_, mental foramina; _e_, vascular impression; _g_, coronoid process; _h_, condyle; _i_, sigmoid notch; _k_, mandibular foramen; _1–7_, cheek teeth, _8_, canine tooth; _9_, _10_, _11_, incisors. (Ellenberger-Baum, Anat d. Haustiere.)]

THE SKULL AS A WHOLE

The =length= and the =profile= contour vary greatly in different subjects. Primitively the skull is long—especially in its facial part—and the frontal profile is almost straight. The condition is very pronounced in wild or semi-feral pigs, and exists also in the improved breeds during extreme youth. Most of the latter are decidedly brachycephalic when fully developed; the face is “dished” in a pronounced fashion. The frontal region slopes sharply upward, and the nasal region is shortened, and in some specimens even distinctly concave in profile. The supraorbital foramina are about midway between the orbital margin and the frontal suture. The supraorbital grooves extend forward from the foramina to the nasal region and turn outward and downward toward the infraorbital foramina over the ridges which separate the nasal and lateral regions.

The =lateral surface= is triangular when the mandible is included. The temporal fossa is entirely lateral and its long axis is almost vertical. It is bounded above by the occipital crest, behind by the temporal crest, in front by the parietal crest, and is marked off from the orbital cavity by the supraorbital process and a curved crest which extends from it to the root of the pterygoid process. The zygomatic arch is strong, high, and flattened from side to side. Its root is notched above and bears a projection below. It curves sharply upward behind and forms a pointed recurved projection above and in front of the external auditory meatus. The orbit is small. Its margin is deficient behind in the dry skull, thick and rounded in front and below. The cavity is limited below by a ridge on the frontal and lacrimal bones, and is separated by a crest from the temporal fossa. The inner wall is perforated above by the orbital opening of the supraorbital canal, and below by the optic and ethmoidal foramina; on its antero-inferior part is the fossa in which the inferior oblique muscle of the eye takes origin. Two lacrimal foramina are found on or close to the anterior margin. The pterygo-palatine fossa is well defined; its upper part forms a deep groove which leads from the large foramen in the sphenoid (like that of the ox) to the very large maxillary foramen. The preorbital region is deeply grooved in its length and is clearly marked off by a ridge from the nasal and frontal regions. The facial crest is short, usually thin-edged, and lies above the fifth and sixth cheek teeth. A little (ca. 2 cm.) in front of it is the infraorbital foramen. There is a ridged prominence over the canine alveolus. In some

skulls the anterior part of the upper jaw is inclined upward.

The most striking features of the =basal surface= are as follows: The paramastoid processes are extremely long, less flattened than in the horse and ox, and nearly vertical. At the inner side of the root of each is the hypoglossal foramen, and in front of it are the stylo-mastoid foramen and a deep cavity in which the hyoid process is concealed. The bulla ossea is long, compressed laterally, and bears a sharp, short, muscular process. The basioccipital is wide and flattened; it bears a median crest and two lateral tubercles. The posterior nares are small and are wider below than above. On either side of them is the tuberosity of the palate bone, and above this is the pterygoid fossa. The palate is remarkably long and is relatively narrow. It constitutes about two-thirds of the entire length of the skull. It is widest between the canines and premolars and narrow at each end. It is marked by a crest medially and by the palatine foramen and groove laterally. The anterior part bears transverse ridges. It is moderately arched from side to side. In some specimens it is nearly straight or slightly concave in its length; in others it curves upward to a variable degree in front. The posterior end always slopes upward more or less.

The =posterior= or =nuchal surface= is remarkable for its height and the breadth of the occipital crest. The central part above the foramen magnum is smooth and concave from side to side, and is bounded laterally by ridges, which converge below and end on two tubercles at the upper margin of the foramen magnum. The surface is separated from the temporal fossæ by the temporal crests, which curve downward and outward and blend with the external auditory canals. The mastoid process has the form of a plate which overlaps the root of the paramastoid process and bears a crest on its anterior part.

The =cranial cavity= is small, in spite of the great size of the cranium; the discrepancy is due to the enormous development of the frontal sinuses in the adult. It is relatively longer, but much lower than that of the ox. Its width is greatly diminished between the orbits. The olfactory fossæ are extensive and very oblique. The floor resembles that of the ox, but the foramen ovale is absent, the dorsum sellæ is more developed, and the foramen lacerum basis cranii is like that of the horse. Two oblique lateral crests clearly mark the limit between the cerebral and cerebellar compartments. The tentorium osseum and the parieto-temporal canals are absent.

The =nasal cavity= is very long. Its posterior part is divided by a horizontal plate into olfactory and respiratory parts. The olfactory part or fundus is above, and contains the ethmoturbinals and ethmoidal meatuses. The lower part is continuous with the inferior meatus and leads to the pharyngeal orifice; hence it is sometimes called the naso-pharyngeal meatus. The bony roof is almost complete in front on account of the great length of the nasal bones.

The =frontal sinus= is a vast excavation in the adult animal. It involves all of the roof and almost all of the sides of the cranium, and extends forward into the roof of the nasal cavity a variable distance—sometimes as far as a transverse plane through the infraorbital foramina. The septum between the right and left sinuses is usually deflected in an irregular manner in its middle part, but is practically median at either end. Each sinus is subdivided by numerous septa, some of which are complete. Thus the sinus is divided into compartments, each of which communicates with an ethmoidal meatus.

In the young pig the sinus is small and is confined to the anterior part of the frontal bone. Later it extends backward, outward, and to a less extent forward. In the old subject it penetrates laterally into the supraorbital process and the root of the zygomatic process of the temporal bone, and behind almost down to the foramen magnum and the occipital condyles. It then consists of six to eight compartments usually.

The =maxillary sinus= is relatively small. Its anterior end is a little less than an inch (ca. 2 cm.) behind the infraorbital foramen, and it extends upward into the lacrimal and backward into the malar bone. The infraorbital canal passes along its floor, and the roots of the molar teeth do not project up into it. It does not communicate with the frontal and sphenoidal sinuses, but with the posterior part of the middle meatus by means of a considerable orifice.

The =sphenoidal sinus= is very large. It involves the body, pterygoid processes, and temporal wings of the sphenoid bone, and extends into the squamous temporal. It communicates with the ventral ethmoidal meatus.

There is a small sinus in the perpendicular part of the palate bone which communicates with an ethmoidal meatus.

BONES OF THE THORACIC LIMB

The =scapula= is very wide, the index being about 1 ■ 0.7. The spine is triangular and is very wide in its middle, which curves backward over the infraspinous fossa and bears a large tuberosity. Its lower part bears a small projection (rudimentary acromion).

The anterior border is strongly convex in profile, sinuous when viewed from the front, and thick and rough in its middle. The posterior border is wide, slightly concave, and bears an outer rough lip. The vertebral border is convex, and the cartilage is not so extensive as in the horse and ox. The cervical angle is thin and bent inward a little. The dorsal angle is thick and is about a right angle. The neck is well defined. The rim of the glenoid cavity is rounded and not notched. The tuberosity is just above the antero-internal part of the glenoid cavity and bears no distinct coracoid process.

The =humerus= has an appearance in profile somewhat like an italic _f_ minus the cross-bar; this is due to the marked backward and forward inclination of the proximal and distal ends respectively. The shaft is decidedly compressed from side to side. The internal surface is extensive and flattened; it is separated from the anterior surface by a distinct border, and bears no teres tubercle. The musculo-spiral groove is shallow. The deltoid tuberosity is small, and there is a larger rounded eminence midway between it and the external tuberosity. The nutrient foramen is on the posterior surface below its middle. The head is more strongly curved and the neck better marked than in the horse or ox. The external tuberosity is very large and extends upon the front of the extremity. It is divided into two high prominences by a wide deep groove. There is a third eminence below and externally for the attachment of the supraspinatus muscle. The bicipital groove is at the front of the inner side; it is undivided and is almost converted into a canal. The outer groove on the distal articular surface is so shallow as to give the appearance of two condyles of similar size. The olecranon fossa is very deep, and the plate of bone which separates it from the coronoid fossa is thin and sometimes perforated. The proximal end unites with the shaft at three and a half years, the distal at one year.

The =radius= is short and narrow, but thick. The shaft increases in size from above downward. The greater part of the posterior surface is in apposition with the ulna; this part is marked by a vascular furrow which runs downward from the upper interosseous space, and has the nutrient foramen at its proximal end. The bicipital tuberosity is represented by a rough area. The distal end is relatively large. Its carpal surface consists of concavo-convex facets for the radial and intermediate carpal bones. There is a wide shallow groove on the middle of the front. The proximal end fuses with the shaft at one year, the distal at three and a half years.

The =ulna= is massive. It is much longer and considerably heavier than the radius. The shaft is curved. The anterior surface is convex and most of it is rough and attached to the radius by the interosseous ligament. There is a smooth area on the upper third, which concurs with the radius in forming the upper interosseous space, and is marked in its upper part by the nutrient foramen. From this space a vascular furrow passes downward to the lower part of the shaft, where there is often a distal interosseous space for the passage of vessels. The internal surface is extensive, concave, and smooth. The external surface is slightly convex, and its upper part is marked by an oblique rough line or ridge. The proximal extremity is large and is bent inward somewhat; its length is more than one-third of that of the entire bone. The distal extremity is relatively small; it articulates with the ulnar and accessory carpal bones, and is notched in front to accommodate the ridge on the radius. The bone contains a considerable medullary canal. The bone is consolidated at three to three and a half years.

The =carpus= comprises eight bones, four in each row. The bones of the proximal row resemble those of the ox, with the exception of the accessory, which is more like that of the horse, but has no external groove. The first carpal is small, elongated from before backward, rounded, and articulates in front with the second carpal. The latter is high and narrow, and articulates with the second and third metacarpal bones below. The third carpal articulates with the radial and intermediate above, the third metacarpal bone below. The fourth is the largest bone of the row; it articulates with the intermediate and ulnar above, the fourth and fifth metacarpals below, and bears a tuberosity on its volar aspect.

[Illustration:

FIG. 113.—SKELETON OF FOREARM AND MANUS OF PIG, ANTERO-EXTERNAL VIEW.

_a_, Radius; _b_, ulna; _c_, radial carpal; _d_, intermediate carpal; _e_, ulnar carpal; _f_, accessory carpal; _g_, first carpal; _h_, second carpal; _i_, third carpal; _k_, fourth carpal; _l-o_, second to fifth metacarpal bones; _p-s_, second to fifth digits; _1_, olecranon; _2_, beak of ulna (proc. anconeus); _3_, semilunar notch; _4_, styloid process of ulna; _5_, styloid process of radius; _6_, distal epiphyseal lines; _7_, first phalanx; _8_, second phalanx; _9_, third phalanx. (Ellenberger-Baum, Anat. d. Haustiere.)]

Four =metacarpal bones= are present. The first is absent, the third and fourth are large and carry the chief digits, while the second and fifth are much smaller and bear the accessory digits. Their proximal ends articulate with each other and with the carpus as indicated above. The bones are consolidated at about two years of age.

The third and fourth metacarpals are flattened from before backward, three-sided, and placed close together. The distal end of each bears a trochlea for articulation with the first phalanx and the sesamoids. The third is the wider of the two, and articulates with all of the lower row of the carpus except the first. The fourth articulates with the fourth carpal chiefly, but has a small facet for the third. The second and fifth metacarpals are placed further back than the chief bones. The fifth is considerably the thicker of the two. The proximal ends are small and articulate with the corresponding carpal and metacarpal bones. The distal end is relatively large; its articular surface is condyloid in front, trochlear behind.

Each chief digit comprises three =phalanges= and three =sesamoids=. The bones of the chief digits resemble those of the ox in form, but there is no foramen on the interdigital side of the extensor process and the proximal sesamoids are narrow and ridged behind. The phalanges of the accessory digits (which do not reach the ground ordinarily) are similar in form but much smaller.

BONES OF THE PELVIC LIMB

The =os coxæ= is long and narrow. The ilium and ischium are almost in line with each other and sagittal in direction. The wing of the =ilium= bends outward much less than in the horse or ox. The gluteal surface is divided into two fossæ by a ridge, which is continuous with the superior ischiatic spine behind. The inner surface presents an extensive rough area behind, which is in apposition with the wing of the sacrum. The smooth iliac area is narrow, and is bounded above by a ridge. The crest or anterior border is convex, and is thick, rough, and prominent in its middle, which forms the highest point of the bone. The internal angle is lower than the crest, is directed backward, and articulates internally with the sacrum. The external angle is lower still and is very little thickened. The =ischia= in the female are somewhat divergent and flattened behind. The tubera are everted and bear three prominences. There is a crest or tuberosity on the ventral surface. The superior ischiatic spine is like that of the cow, but is slightly incurved and the muscular ridges on its outer face are more pronounced. The symphyseal part of the =pubis= is thick and the two bones are almost in a horizontal plane. The ilio-pectineal eminence is prominent and the psoas tubercle is well marked.

The =acetabulum= is placed a little further back than in the ox. The rim is thick and is cut into posteriorly by a narrow fissure, which leads into the deep fossa acetabuli. The three pieces of the os coxæ are fused by the end of the first year, but the crest and the ischial tubera are partially separate till the sixth or seventh year. The symphysis does not usually undergo complete anchylosis. Interischial bones are present.

The =inlet= of the =pelvis= is elliptical and very oblique. In a sow of full size the conjugate diameter is about five to six inches (10 to 12 cm.) and the transverse about three and a half to four inches (ca. 8.75 to 10 cm.). In the female the floor is relatively wide and flattened, especially at the outlet, where the tubera are everted; it also has a decided downward inclination behind. The pelvic axis is therefore correspondingly oblique. The ischial arch is wide. In the boar the pubis is much thicker and the ischia are not everted posteriorly. The inlet is smaller. The floor is concave from side to side and slopes decidedly less than in the sow. The superior ischiatic spines are more incurved, and the ischial arch is much narrower and deeper.

The =femur= has a relatively wide and massive shaft, on which four surfaces might be recognized. The principal nutrient foramen is situated in the proximal third of the anterior surface. The posterior surface is wide, and is limited outwardly by a ridge which extends from the trochanter major to the large external supracondyloid crest. There is no supracondyloid (plantar) fossa. The head is strongly curved, and is marked toward the inner side by a rather large depression for the attachment of the round ligament. The neck is distinct. The trochanter major, although massive, does not extend up as high as the head. The trochanteric ridge and fossa resemble those of the ox. The external (third) trochanter is absent. The ridges of the trochlea are similar and almost sagittal.

The shaft of the =tibia= is slightly curved, convex internally. The tuberosity is grooved in front, and a narrow sulcus separates it from the external condyle. The facet for the fibula is on the posterior border of the latter, and is bounded internally by an eminence. The upper part of the crest is very prominent and curves outward. The distal end resembles in general that of the ox, but is relatively narrower transversely and thicker from before backward.

The =fibula= extends the entire length of the region, and is separated from the tibia by a wide interosseous space. The shaft is flattened from side to side; the proximal part is wide and deeply grooved externally; the lower part is narrower and thicker. The proximal end is flattened, grooved externally, and articulates internally with the external condyle of the tibia. The distal end forms the external malleolus. It is grooved externally, and articulates with the tibia and tibial tarsal internally, with the fibular tarsal bone distally.

The =patella= is very much compressed laterally and presents three surfaces.

[Illustration:

FIG. 114.—COXAL BONES OF PIG, LEFT POSTERIOR VIEW.

_a_, Wing, _b_, shaft, _c_, external angle, _d_, anterior border, _e_, internal angle, _f_, gluteal line of ilium; _g_, great sciatic notch; _h_, smooth, _i_, rough part of ventral surface of ilium; _k_, psoas tubercle; _l_, ilio-pectineal eminence; _m_, acetabular branch, _n_, symphyseal branch of pubis; _o_, obturator foramen; _p_, _p′_, ischium; _q_, _q′_, tuber ischii; _r_, symphysis; _s_, ischial arch; _t_, _t′_, superior ischiatic spine; _u_, acetabulum; _v_, epiphyseal line. (Ellenberger-Baum, Anat. d. Haustiere.)]

The =tarsus= comprises seven bones. The tibial and the fibular tarsal resemble in general those of the ox. The axis of the tibial is, however, slightly oblique downward and inward, and its distal end bears a double trochlea for articulation with the central and fourth tarsals. The tuber calcis is deeply grooved posteriorly. The central tarsal is narrow transversely and thick. Its proximal surface is deeply concave, and the posterior bears a large tubercle. The first tarsal is high and narrow; it articulates with the central and second tarsals and the second metatarsal bone. The second tarsal is small and somewhat prismatic; it articulates with the central above, the third in front, the first behind, and the second and third metatarsals below. The third tarsal is much larger, and is compressed from above downward, wide in front, narrow behind. It articulates with the central tarsal above, the third metatarsal below, the second tarsal internally, and the fourth tarsal externally. The fourth tarsal is large. Its external face is crossed by an oblique groove for the tendon of the peroneus longus. The internal surface articulates with the central and third tarsals. The proximal surface supports the tibial and fibular tarsal bones, and the distal surface rests on the fourth and fifth metatarsals. It ossifies from two centers.

The four =metatarsal bones= resemble the corresponding bones of the fore limb, but are somewhat longer. The proximal ends of the third and fourth each have a considerable projection behind; the process on the third has a facet for articulation with a discoid sesamoid bone. The second and fifth are placed more on the posterior aspect of the large bones than is the case in the fore limb.

The first and second =phalanges= are a little longer and narrower than those of the fore limb.

SKELETON OF THE DOG

VERTEBRAL COLUMN

The vertebral formula is $C_{7}T_{13}L_{7(6)}S_{3}Cy_{20–23}$.

The =cervical vertebræ= are relatively longer than in the ox and the pig. The bodies of the typical vertebræ diminish in length from first to last and are compressed dorso-ventrally. The anterior extremity is moderately convex and the posterior slightly concave; both are oblique. The median ridge and lateral grooves on the upper surface of the body are very well marked. The second, third, and fourth have distinct ventral spines. The spinous process of the third has the form of a long low crest; in the remainder it is higher, blunt-pointed, and inclined forward. The transverse processes of the third, fourth, and fifth project downward and backward, and divide into two branches; of these, the anterior one is thin, and the posterior is thick and tuberculate at its free end. The process of the sixth has two parts; one of these is an extensive quadrilateral plate directed downward and outward and ridged on its inner surface; the other part is short and blunt, and is directed outward and a little backward and upward. The seventh is readily distinguished by its shortness, the length of its spine, and the single transverse process. The posterior articular processes bear tubercles which are large on the third, fourth, and fifth.

The ventral arch of the =atlas= is narrow from before backward, and bears a small tubercle posteriorly. The upper surface of the dorsal arch is strongly convex and rough centrally. The wings are wide, flattened, and almost horizontal. The upper surface is rough. There is an alar notch (Incisura alaris) on the anterior border instead of the anterior foramen. The foramen transversarium is present.

The body of the =axis= is flattened dorso-ventrally, especially in front. The odontoid process is rounded and relatively long, reaching almost to the occipital bone; it is inclined upward a little. The articular surfaces which flank it are condyloid in form and very oblique. The inferior surface is wide, and is divided by a median crest into two fossæ. The transverse processes are single, pointed, directed backward and outward, and perforated by relatively large foramina transversaria. The spinous process is thin and of moderate height, but very long; it is prolonged forward so as to overhang the dorsal arch of the atlas, and is terminated behind by a tuberosity which is connected by two crests with the posterior articular processes. The anterior notches are large and are never converted into foramina.

The bodies of the =thoracic vertebræ= are wide and compressed dorso-ventrally, especially at each end of the region. Their convex anterior surfaces are depressed in the middle. The posterior facets for the heads of the ribs are absent on the last three or four. The transverse processes resemble those of the horse. They bear mammillary processes except at the anterior end of the region. The facets for the tubercles of the ribs are large and concave in the anterior part of the series, and become smaller and slightly convex further back. The last three have accessory processes also. The first three or four spinous processes are about equal in length. Behind this they become gradually shorter to the tenth, and then remain equal. The backward slope is most marked in the ninth and tenth. The eleventh is practically vertical (anticlinal vertebra) and the last two incline slightly forward.

The bodies of the =lumbar vertebræ= are decidedly flattened dorso-ventrally, and increase in width from first to last. The length increases to the sixth. The transverse processes are plate-like and are directed forward and downward. Their length increases to the fifth and sixth. They form no joints with each other or with the sacrum. Their extremities are enlarged, with the exception of the last. The accessory processes project backward over the posterior notches of the first five. The anterior articular processes are large, compressed laterally, and bear mammillary processes. The spinous processes are broad below, narrower above, and with the exception of the last, incline a little forward. Their height diminishes behind the fourth.

[Illustration:

FIG. 115.—SKELETON OF DOG, LATERAL VIEW.

_a_, Cranium; _b_, face; _c_, mandible; _1H-7H_, cervical vertebræ; _13B_, last thoracic vertebra; _1L-7L_, lumbar vertebræ; _K_, sacrum; _S_, coccygeal vertebræ; _1R-13R_, ribs; _R.Kn._, costal cartilages; _St._, sternum; _d_, scapula; _d′_, supraspinous fossa; _d″_, infraspinous fossa; _1_, spine of scapula; _2_, acromion; _3_, tuberosity of scapula; _3′_, articular end of scapula; _e_, humerus; _4_, head of humerus; _5_, external tuberosity of humerus; _5′_, deltoid ridge; _6_, _6′_, epicondyles of humerus; _7_, external condyloid crest; _7′_, coronoid fossa; _f_, radius; _g_, ulna; _8_, olecranon; _9_, “beak” of ulna; _h_, carpus; _i_, metacarpus; _k_, proximal phalanges; _l_, middle phalanges; _m_, distal phalanges; _n_, sesamoid; _p_, ilium; _10_, wing of ilium; _11_, shaft of ilium; _12_, crest of ilium; _13_, external angle of ilium (tuber coxæ); _14_, internal angle of ilium (tuber sacrale); _15_, superior ischiatic spine; _q_, pubis; _r_, ischium; _16_, tuber ischii; _17_, acetabulum; _s_, femur; _18_, head of femur; _19_, trochanter major; _20_, trochanter minor; _21_, trochanter tertius; _22_, _23_, condyles; _24_, _25_, epicondyles; _26_, trochlea; _t_, patella; _u_, tibia; _27_, tuberosity of tibia; _28_, _29_, condyles of tibia; _30_, internal malleolus; _v_, fibula; _31_, external malleolus; _32_, head of fibula; _w_, tarsus; _x_, metatarsus; _y_, phalanges; _33_, occipital bone; _34_, paramastoid (styloid) process; _35_, parietal bone; _36_, frontal bone; _37_, lacrimal bone; _38_, malar bone; _39_, squamous temporal; _40_, maxilla; _40′_, infraorbital foramen; _41_, premaxilla; _42_, nasal bone; _43_, external auditory meatus; _44_, canine tooth; _45_, masseteric fossa; _46_, angular process of mandible. (After Ellenberger, in Leisering’s Atlas.)]

The =sacrum= results from the early fusion of three vertebræ. It is short, wide, and quadrangular. The spines are fused to form a median crest, which is notched, however, between the summits of the spines. On either side are two tubercles, vestiges of the fused articular processes. The pelvic surface is deeply concave and presents two pairs of foramina. The wings are prismatic and very high. Their lateral surfaces are extensive, face almost directly outward, and bear an auricular surface on the lower part. The anterior surface of the body of the first vertebra is extensive, depressed in its middle, and bears a prominent lip below. The anterior articular processes are large and have extensive, slightly concave facets which face upward and inward. The posterior articular processes are small. The transverse processes of the last vertebra project backward and may articulate or fuse with those of the first coccygeal. The sacral canal is strongly compressed dorso-ventrally.

[Illustration:

FIG. 116.—ATLAS OF DOG, VIEWED FROM ABOVE AND BEHIND.

_a_, Wing; _b_, dorsal arch and tubercle; _c_, ventral tubercle; _d_, intervertebral foramen; _e_, foramen transversarium; _f_, articular surface for axis. (Ellenberger-Baum, Anat. d. Hundes.)]

[Illustration:

FIG. 117.—AXIS OF DOG, LEFT LATERAL VIEW.

_a_, Odontoid process; _b_, articular surface for atlas; _c_, transverse process; _d_; foramen transversarium; _d′_, posterior opening of _d_; _e_, spine; _f_, posterior articular process. (Ellenberger-Baum, Anat. d. Hundes.)]

The =coccygeal vertebræ= are fully developed in the anterior part of the region. The arch is complete in the first six usually. The first three or four have well developed articular processes at each end. Behind this the posterior pair quickly disappears, and the anterior ones become non-articular and gradually reduced in size. The transverse processes of the first five or six are relatively large; behind this they quickly disappear. =Hæmal arches= (or chevron bones) in the form of a =V= or =Y= occur ventrally at the intercentral junctions of the third, fourth, and fifth usually. They transmit the middle coccygeal artery, which passes between pairs of ventral tubercles further back.

FIG. 119.—FOURTH THORACIC VERTEBRA OF DOG, LEFT VIEW.

_a_, Head; _b_, glenoid cavity; _c_, facet for head of rib; _d_, transverse process; _e_, facet for tubercle of rib; _f_, mammillary process; _g_, posterior articular process; _h_, spinous process. (Ellenberger-Baum, Anat. d. Hundes.)]

=Curves.=—A gentle curve, convex ventrally, is formed by the cervical and the anterior part of the thoracic region. The posterior thoracic and the lumbar vertebra form a second curve, concave ventrally. The sacral promontory is well marked. The sacrum and the anterior part of the coccygeal region constitute a third and more pronounced curve, concave ventrally. In long-tailed dogs the sacro-coccygeal region is somewhat =S=-shaped.

=Variations.=—Numerical variations are not common except in the coccygeal region. The number of thoracic vertebræ may be twelve or fourteen, with or without compensatory change in the lumbar region. Girard recorded a case with eight lumbar and the usual number of thoracic vertebra. Six lumbar with fourteen thoracic vertebræ have been met with. The first coccygeal sometimes unites with the sacrum.

THE RIBS

Thirteen pairs of ribs are present, of which nine are sternal and four asternal. They are strongly curved, narrow, and thick. Those in the middle of the series are the longest. The first eight or nine increase in width in their lower part. The last rib is usually floating. The costal cartilages are long and curve forward; the length and curvature of the first pair is a striking special feature.

[Illustration:

FIG. 120.—FOURTH LUMBAR VERTEBRA OF DOG, LEFT VIEW.

_a_, _b_, Articular surfaces of body; _c_, transverse process; _d_, accessory process; _e_, anterior articular process; _e′_, mammillary process; _f_, posterior articular process; _g_, spinous process. (Ellenberger-Baum, Anat. d. Hundes.)]

FIG. 121.—SACRUM OF DOG, DORSAL VIEW.

_a_, Dorsal sacral foramina; _b_, articular surface of body of first segment; _c_, _d_, anterior articular processes; _e_, wing; _f_, rudiments of articular processes; _g_, lateral part; _h_, spinous processes. (Ellenberger-Baum, Anat. d. Hundes.)]

THE STERNUM

This is long, laterally compressed, and consists of eight sternebræ, which fuse only in exceptional cases and in extreme old age. The first segment is the longest; its anterior end is blunt-pointed and bears a short conical cartilage. It widens at the point of articulation of the first pair of cartilages. The last segment is also long, thinner than its predecessors, wide in front, and narrow behind, where it bears a narrow xiphoid cartilage.

The =thorax= is distinctly barrel-like and is not decidedly compressed anteriorly like that of the horse and ox. The inlet is oval and is relatively wide on account of the marked curvature of the first pair of ribs and cartilages.

BONES OF THE SKULL

In the following descriptions of the separate bones an intermediate type—_e. g._, a fox terrier—is selected, and the most striking differences in the brachycephalic and dolichocephalic breeds will be considered in the section on the skull as a whole.

CRANIUM

[Illustration:

FIG. 122.—BASE OF SKULL OF DOG, WITHOUT MANDIBLE.

_I_, Occipital; _II_, tympanic part of temporal; _IIa_, squamous part of temporal; _IIb_, mastoid part of temporal; _III_, sphenoid; _IV_, pterygoid; _V_, palate bone; _VI_, vomer; _VII_, malar; _VIII_, zygomatic arch; _IX_, inner wall of orbit; _X_, palatine process of maxilla; _XI_, premaxilla; _XII_, orbital cavity; _1_, _1_, tubercles above foramen magnum; _2_, foramen magnum; _3_, occipital condyle; _4_, notch between occipital condyles; _5_, condyloid fossa; _6_, hypoglossal foramen; _7_, paramastoid (styloid, jugular) process; _8_, for. lacerum and posterior opening of carotid canal; _9_, petro-occipital synchondrosis; _10_, petro-tympanic fissure; _11_, tubercle; _12_, bulla ossea; _13_, muscular process of petrous; _14_, carotid foramen; _15_, osseous Eustachian tube; _16_, postglenoid process; _17_, glenoid cavity; _18_, for. ovale; _19_, posterior opening of alar canal; _20_, external opening of parieto-temporal canal; _21_, stylo-mastoid foramen; _22_, external auditory meatus; _23_, temporal crest; _24_, zygomatic process of temporal bone; _25_, body of postsphenoid; _26_, body of presphenoid; _27_, anterior opening of alar canal; _28_, for. lacerum orbitale; _29_, optic foramen; _30_, hamulus of pterygoid; _31_, horizontal part of palate bone; _32_, perpendicular part of palate bone; _33_, median palatine suture; _34_, palato-maxillary suture; _35_, posterior nasal spine; _36_, anterior palatine foramen; _37_, palatine groove; _38_, alveolar border of maxilla; _39_, palatine process of maxilla; _40_, pterygoid process of maxilla; _41_, palatine fissure; _42_, body of premaxilla; _43_, palatine process of premaxilla; _44_, alveolar border of premaxilla; _45_, supraorbital process of frontal bone. (Ellenberger-Baum, Anat. d. Hundes.)]

The =occipital bone= is similar in position to that of the horse. The crest, is prominent, angular, and directed backward. Just below the crest are two rough imprints or tubercles for muscular attachment. The surface below these is convex from side to side and concave from above downward. On either side, at the junction with the squamous, there is a foramen which communicates with the parieto-temporal canal. The condyles are somewhat flattened and are widely separated above; at the inner side of each is a short condyloid canal, which opens into the parieto-temporal canal. The paramastoid processes are very short. The basilar part is wide and joins the bulla ossea on either side; its lower surface is flattened and the tubercles are at the junction with the bulla. The hypoglossal foramen is small and is close to the foramen lacerum posterius; the latter is bounded in front by the bulla ossea, behind and internally by the occipital bone.

The =interparietal bone= fuses with the occipital before birth. It forms the high posterior part of the sagittal crest, and is wedged in between the two parietal bones. The tentorium osseum is thin and curved, concave ventrally. Its base concurs with the occipital and parietal bones in the formation of a transverse canal which is continuous with the parieto-temporal canals.

[Illustration:

FIG. 123.—SKULL OF DOG, DORSAL VIEW.

_I_, Occipital; _II_, parietal; _III_, frontal; _IV_, lacrimal; _V_, malar; _VI_, squamous temporal; _VII_, nasal; _VIII_, maxilla; _IX_, premaxilla; _1_, supraoccipital; _2_, interparietal; _3_, parieto-occipital suture; _4_, occipital crest; _5_, sagittal crest; _6_, parieto-frontal suture; _7_, squamous suture; _8_, parietal eminence; _9_, antero-external angle of parietal bone; _10_, frontal crest; _11_, _14_, orbital margin; _12_, supraorbital process; _13_, frontal fossa; _15_, temporal part of frontal bone; _16_, nasal process of frontal bone; _17_, frontal suture; _18_, lacrimal foramen; _19_, maxillary process of frontal bone; _20_, lacrimo-maxillary suture; _21_, frontal process of malar bone; _22_, lacrimal process of malar; _23_, zygomatic process of malar; _24_, zygomatic process of squamous temporal; _24′_, posterior end of nasal bone; _25_, nasal suture; _26_, anterior end of nasal bone; _27_, infraorbital foramen; _28_, canine tooth; _29_, cheek tooth; _30_, frontal process of maxilla; _31_, body, _32_, nasal process, _33_, palatine process of premaxilla; _34_, palatine fissure; _35_, incisor teeth. (Ellenberger-Baum, Anat. d. Hundes.)]

The =parietal bone= is rhomboid in outline and is strongly curved. It is extensive and forms the greater part of the roof of the cranial cavity. At the junction of the right and left bones there is a prominent sagittal crest which is continued upon the frontal bones. The lower border articulates with the temporal wing of the sphenoid by its anterior part and with the squamous temporal in the remainder of its extent. The external surface enters into the formation of the temporal fossa. The internal surface is marked by digital impressions, and by grooves for the middle meningeal artery and its branches.

The external surface of the =frontal bone= is crossed by a frontal crest, which extends in a curve from the sagittal crest to the supraorbital process, and separates the frontal and temporal parts. The frontal parts of the two bones form a central depression and slope downward and forward. The supraorbital process is very short, so that the orbital margin is incomplete as in the pig. The supraorbital foramen is absent. In front there is a narrow pointed nasal part which fits in between the nasal bone and the maxilla. The orbital and temporal parts are relatively extensive. Two ethmoidal foramina are commonly present. The frontal sinus is confined to the frontal bone.

The parts of the =temporal bone= fuse early. The zygomatic process curves widely outward and forward. Its anterior part is beveled below and articulates extensively with the corresponding process of the malar. The articular surface for the condyle of the mandible consists of a transverse groove which is continued upon the front of the large postglenoid process. Behind the latter is the lower opening of the parieto-temporal canal. There is no condyle. The mastoid part is small, but bears a distinct mastoid process. The external auditory meatus is large and the canal very short, so that one can see into the tympanum in the dry skull. The India ossea is very large and is rounded and smooth; the inner side is united to the basioccipital. Above this junction and roofed in by the union of the petrous part and the basioccipital is the =petro-basilar canal= (Canalis petrobasilaris); this transmits a vein from the floor of the cranium to the foramen lacerum posterius. The latter is in reality a depression and is situated behind the bulla ossea. In its posterior part is a foramen which transmits the ninth, tenth, and eleventh cranial nerves. The =carotid canal= branches off from the petro-basilar, passes forward external to it through the inner part of the bulla ossea, and opens in front at the =carotid foramen=; it transmits the internal carotid artery. The Eustachian opening is immediately external to the carotid foramen. The muscular and hyoid processes are extremely rudimentary. The petrous part projects into the cranial cavity and forms a sharp prominent petrosal crest. The inner surface presents a deep =floccular fossa= above the internal auditory meatus. The anterior surface is also free. The anterior angle is perforated by a =canal= for the fifth cranial nerve (Canalis nervi trigemini).

[Illustration:

FIG. 124.—CRANIAL CAVITY OF DOG, AS SEEN ON SAGITTAL SECTION OF SKULL.

_I_, Roof of cranium; _II_, base of cranium; _III_, posterior wall of cranium; _IV_, anterior wall of cranium; _A_, anterior cranial fossa; _B_, middle cranial fossa; _C_, posterior cranial fossa; _a_, body of presphenoid; _a′_, body of postsphenoid; _c_, palate bone; _d_, vomer; _e_, occipital; _f_, occipital condyle; _g_, sagittal crest; _h_, frontal sinus; _h′_, cranial plate of frontal bone; _i_, cribriform plate of ethmoid bone; _i′_, ethmoidal foramen; _k_, ethmoturbinals; _l_, parietal bone; _l′_, _l″_, squamous temporal bone; _l■_, temporal wing of sphenoid bone; _m_, sella turcica; _m′_, dorsum sellæ; _n_, optic foramen; _o_, foramen lacerum orbitale; _p_, foramen rotundum; _q_, foramen ovale; _r_, _r′_, carotid foramina; _s_, tentorium osseum; _t_, foramen lacerum; _u_, _u′_, orifices of parieto-temporal canal; _v_, condyloid canal; _w_, canal for trigeminal nerve; _x_, internal auditory meatus; _y_, _y′_, orifices of canal for inferior occipital sinus; _z_, floccular fossa. (After Ellenberger, in Leisering's Atlas.)]

The body of the =sphenoid bone= is flattened dorso-ventrally. The sella turcica is shallow, but the dorsum sellæ is well developed and bears =posterior clinoid processes=. A pair of =anterior clinoid processes= project back from the roots of the orbital wings. The latter are relatively small and are crossed externally by a crest, which is continued forward upon the palate bone. The temporal wings are extensive and articulate above with the parietals. Perforating the roots of the wings are the following foramina, named from before backward: The optic passes through the orbital wing. The foramen lacerum orbitale is a little lower and is at the junction of the wings. The foramen rotundum opens into the alar canal, which passes through the root of the short but wide pterygoid process. The foramen ovale is near the posterior border of the temporal wing. There is no sphenoidal sinus.

The =ethmoid bone= is highly developed. The cribriform plate is extensive, and the olfactory fossæ are very deep. The crista galli is little developed, and often incomplete. The perpendicular plate is long. The lateral masses are greatly developed and bulge upward into the frontal sinus. There are four large endoturbinals and six ectoturbinals. The lamina papyracea is extensive and forms the inner wall of the maxillary sinus. Its lower border joins the palatine process of the maxilla and the horizontal part of the palate bone. A shelf-like plate extends inward from its lower part and concurs with the similarly incurved part of the palate bone in forming the

=transverse lamina= (Lamina transversalis), which divides the olfactory fundus of the nasal cavity from the naso-pharyngeal meatus.

FACE

The =maxilla= is short, but very high posteriorly. The facial crest is absent. The infraorbital foramen is over the alveolus for the third premolar. The =frontal process= fits into a deep notch between the nasal and orbital parts of the frontal bone, and the middle part of the posterior border lies along the orbital margin. There are more or less pronounced ridges, juga alveolaria, over the canine and molar teeth. The zygomatic process is short and thin; it is completely overlapped outwardly by the malar, and is perforated by a number of foramina (Foramina alveolaria). A maxillary tuberosity is not present in the adult, but there is a pointed projection, the pterygoid process, behind the last alveolus. The internal surface bears a short turbinal crest on its anterior part, behind which it is deeply concave and forms the outer wall of the maxillary sinus. The palatine process is short, wide behind, and moderately arched from side to side. The anterior palatine foramen is situated at or close to the transverse palatine suture about midway between the median suture and the alveolar border. The palatine groove is distinct. The large alveolus for the canine tooth is completed by the premaxilla. The small alveolus for the first premolar is separated from the preceding one by a small interval. The next two consist of anterior and posterior parts for the roots of the teeth. The fourth and fifth are much larger and are divided into three parts. The last is small and consists of three divisions. The infraorbital canal is short.

The body of the =premaxilla= is compressed dorso-ventrally, and contains three alveoli for the incisor teeth, which increase in size from first to third; it also completes the inner wall of the large alveolus for the canine tooth. The foramen incisivum is very small except in large skulls. The interalveolar border is wide and very short. The nasal process is wide at its origin and tapers to a sharp point behind; the anterior part curves upward, backward, and a little inward, and forms the lateral margin of the osseous nasal aperture; the posterior part extends backward a long distance between the nasal bone and the maxilla. The palatine process turns upward and outward, forming with its fellow a wide groove for the septal cartilage; the posterior end is pointed and fits into a notch between the palatine processes of the maxillæ, and supports the end of the vomer. The palatine fissure is short but wide.

The horizontal part of the =palate bones= is extensive, forming about one-third of the hard palate. It presents a variable number of lesser palatine foramina. There is usually a pointed posterior nasal spine at the end of the median suture. The palatine canal is sometimes formed entirely in this bone. The perpendicular part is even more extensive. Its external surface is chiefly free and forms most of the inner wall of the large pterygo-palatine fossa. The maxillary foramen is situated in a deep recess between this bone and the zygomatic process of the maxilla. Just above it there is commonly another foramen which opens into the nasal cavity. The posterior palatine and sphenopalatine foramina are situated further back and a little lower; the former is immediately below the latter. A horizontal plate extends from the inner surface, meets that of the opposite bone and completes the lamina transversalis spoken of in the description of the ethmoid bone. There is no palatine sinus.

The =pterygoid bones= are very wide and short. They form a considerable part of the lateral boundaries of the posterior nares. The lower and posterior holders are free and at their angle of junction there is a variable hamulus.

The =nasal bones= are (in most breeds) long and wider in front than behind. The external surface is variably concave in its length and is inclined toward the median suture so as to form a central groove. The inner borders turn downward and form an internal nasal crest which becomes very prominent behind. The posterior parts fit into a notch formed by the frontal bones. The anterior ends form an almost semicircular nasal notch.

The =lacrimal bone= is very small. The facial part extends very little or not at all beyond the orbital margin. The orbital surface is small and triangular, and presents the entrance to the lacrimal canal.

[Illustration:

FIG. 125.—MANDIBLE OF DOG, RIGHT-ANTERIOR VIEW.

_a_, Right ramus; _b_, left ramus; _c_, body; _d_, alveolar border; _e_, processus angularis; _f_, condyle; _g_, coronoid process; _h_, masseteric fossa; _i_, _k_, crests which form the upper and lower boundaries of fossa; _l_, mandibular foramen; _m_, mental foramina; _n_, masseteric line; _o_, sigmoid notch. (Ellenberger-Baum, Anat. d. Hundes.)]

The large zygomatic process constitutes the bulk of the =malar bone=. It is very long and is strongly curved. The upper border is convex, free in front, where it forms part of the orbital margin, beveled behind for articulation with the similar process of the

temporal bone. Between these it bears an eminence, the processus frontalis, to which the orbital ligament is attached. The body of the bone may be considered to consist of a =lacrimal process= directed upward and fitting in between the lacrimal and maxilla, and a =maxillary process= directed downward. The facial surface is convex.

The =superior turbinal bone= is in its anterior part a simple plate, attached by one edge to the nasal bone; it curves downward and inward, and its free border is thickened and everted. The posterior part is wider and resembles the ethmoturbinals, with which it is connected.

The =inferior turbinal bone= is short and very complex. It is attached to the nasal surface of the maxilla by a basal lamina, which divides into two secondary lamellæ. The latter detach numerous tertiary lamellæ, which are coiled and have thick free edges (Fig. 373).

The =vomer= is not in contact with the posterior part of the floor of the nasal cavity, and does not divide the posterior nares. The posterior end is narrow and deeply notched. Near the posterior nares the two plates curve outward and join the palate bones and assist in forming the lamina transversalis.

The two halves of the =mandible= do not fuse completely even in old age. The body presents six alveoli for the incisor teeth and two for the canines. The incisor alveoli increase in size from first to third. The canine alveoli extend deeply downward and backward. There are usually two or more foramina on the mental surface. The rami diverge less than in the pig. The inferior border of the horizontal part is convex in its length and is thick and rounded. The alveolar border slightly concave in its length and is a little everted, especially in its middle; it presents seven alveoli for the lower cheek teeth, which resemble those of the upper jaw except that the fourth and sixth are much smaller and the fifth is like the fourth of the upper series. The interalveolar space is very short or even absent. There are two or three mental foramina on either side. The vertical part is relatively small. Its external surface presents a deep =masseteric fossa= which encroaches on the coronoid process and is limited by ridges in front and below. The internal surface is convex and is marked by the usual foramen. At about the same level as the latter is the rough =angular process= (Processus angularis), which projects backward from the posterior border, and is equivalent to the angle of the other animals. The condyle is placed very low—not much higher than the apex of the canine tooth when the bone is resting on a flat surface. It is long transversely and the inner part of the articular surface is much the wider and extends over the posterior surface. Its long axis is a little oblique, the inner end being inclined somewhat downward and forward. The coronoid process is very extensive and is bent slightly outward and backward.

The body of the =hyoid bone= is a slightly curved transverse rod; it is compressed from before backward, and bears no lingual process. The thyroid cornua are permanently attached to the body by cartilage; they diverge widely, curve inward, and are compressed laterally. The small cornua are short, prismatic, and strong. The middle cornua are commonly a little longer than the great cornua; they are compressed laterally, and are slightly enlarged at the ends, which are joined by cartilage to the adjacent cornua. The great cornua are bent outward and are somewhat twisted.

THE SKULL AS A WHOLE

The different breeds of dog display great variations in the form and size of the skull. Those which have a long narrow skull (_e. g._, greyhound, collie) are designated =dolichocephalic=. Other dogs (_e. g._, bulldog, small spaniels, pugs) have very broad, short skulls and are termed =brachycephalic=. Intermediate forms (e. g., fox terrier, dachshund) are =mesaticephalic=.

The length is usually measured from the occipital crest to the anterior end of the premaxillary suture, and the breadth between the summits of the zygomatic arches. The cephalic index is the relation of the breadth to the length, assuming the latter equal 100; the formula is: (breadth × 100)/(length) = cephalic index. The index of extreme dolichocephalic breeds is about 50 or even less, as in the greyhound, and that of brachycephalic specimens may be as high as 90, as in the bulldog and pugs. Among the mesaticephalic types are the fox terrier, with an index of about 70, and the white Pomeranian, with one about 72 to 75. The cranio-facial index is the relation of the distance from the occipital crest to the fronto-nasal suture to that between the latter and the nasal notch. It varies from 10 ■ 3 in extreme brachycephalic breeds to 10 ■ 7 in extreme dolichocephalic subjects.

The =superior surface= shows the wide outward curve of the zygomatic arches, and the great extent of the temporal fossæ. The latter are separated by the sagittal crest, which in the larger breeds is very strong and prominent, and is continued by the diverging frontal ridges to the supraorbital processes. The frontal and nasal regions are centrally depressed, and are more or less concave in profile. The nasal region is narrow and is terminated in front by a nasal notch. In the extreme brachycephalic breeds the differences

are very striking. The cranium is strongly convex in both directions and is considerably longer than the face. The sagittal crest is more or less effaced and is formed by the interparietal only. The parieto-frontal crests are separated by an interval behind and diverge to the supraorbital processes, so that the temporal fossæ are widely separated. The frontal region is wide, strongly convex, and has a shallow central depression. The nasal region is very short, relatively wide, and centrally depressed. In profile there is a marked depression at the fronto-nasal junction, producing what is termed by fanciers the “stop” of the face.

On the =lateral surface= the great extent of the temporal fossa is seen. The orbit communicates freely with the fossa, the posterior part of the orbital margin being absent in the dry skull. The axis of the orbital cavity forms a much smaller angle with the median plane than in the horse and ox. A distinct crest marks the limit between the orbital cavity proper and the extensive pterygo-palatine fossa. The preorbital region is somewhat triangular, concave in its length, and convex from above downward. The infraorbital foramen is on its lower part above the third cheek tooth. In extreme brachycephalic breeds the orbit is relatively very large and the preorbital region extremely short but high. In the bulldog the lower jaw protrudes beyond the upper—a condition known as prognathism. The opposite condition, brachygnathism, is seen in the dachshund.

[Illustration:

FIG. 126.—SKULL OF BRACHYCEPHALIC DOG, DORSAL VIEW WITHOUT MANDIBLE.]

Striking features on the =basal surface= of the cranium are the width and flatness of the basioccipital, the small size of the paramastoid processes, the large size and rounded shape of the bulla ossea, and the grooved form of the articular surfaces for the mandible. The posterior nares are long and narrow and are not divided by the vomer. The hard palate is usually about half the length of the skull. It is commonly marked by a median crest or rough line, and on each side are the anterior and accessory palatine foramina and the palatine grooves. The width is greatest between the fourth pair of cheek teeth, and here there is in most skulls a pronounced depression on either side. The length, width, and contour vary greatly in different breeds.

The angle of divergence of the rami of the mandible varies from 25 to 30 degrees; it is smallest in the greyhound, largest in extreme brachycephalic types, _e. g._, bulldog, pug.

The =posterior= or =nuchal surface= is somewhat triangular, with the base below. The summit is formed by the occipital crest, which projects very strongly backward in the large breeds. Below it there are two very distinct rough imprints for muscular attachment. In some skulls there is a thin median crest, in others a rounded elevation. Laterally are the temporal crests and the mastoid processes. There is usually a foramen in the temporo-occipital suture above the root of the paramastoid process. The foramen magnum varies greatly in form; most often the transverse diameter is the greater, but in some skulls it is equaled or exceeded by the vertical diameter.

The =cranial cavity= (Fig. 124) corresponds in form and size with the cranium, specially in those breeds in which the various crests are more or less effaced and the frontal sinuses are small. The basi-cranial axis is almost parallel with the palate, and the floor is flattened. The anterior fossa is narrow and is only slightly higher than the middle one. The olfactory fossæ are very deep and the crista galli is little developed. The sella turcica is variable in depth, and the dorsum sellæ is relatively high and bears clinoid processes laterally. The cerebral and cerebellar compartments are well marked off laterally by the petrosal crests and above by the tentorium osseum. The base of the latter is traversed by a canal which connects the two parieto-temporal canals. The anterior angle of the petrous temporal is perforated by a canal for the fifth cranial nerve.

[Illustration:

FIG. 127.—SKULL OF BRACHYCEPHALIC DOG, LATERAL VIEW WITHOUT MANDIBLE.]

The =nasal cavity= (Fig. 373) conforms to the shape of the face. Its anterior aperture is large and nearly circular in most dogs. The complex inferior turbinals occupy the anterior part of the cavity to a large extent, except near the aperture. Behind the inferior turbinals is the large opening of the maxillary sinus. Behind this the cavity is divided by a horizontal plate (Lamina transversalis) into a large upper olfactory region or fundus nasi and a lower naso-pharyngeal canal. The fundus is occupied largely by the ethmoturbinals. The posterior nares are undivided and are in general long and narrow, but vary with the shape of the skull.

The =frontal sinus= is of considerable size in the large breeds, but is confined to the frontal bone. It is usually divided into a small anterior and a much larger posterior compartment, each of which opens into the superior ethmoidal meatus. The sinus is very small in extreme brachycephalic types.

The =maxillary sinus= is small, and is in such free communication with the nasal cavity as to make it rather a recess than a true sinus. It is bounded internally by the lamina papyracea of the ethmoid, and its outer wall is crossed obliquely by the lacrimal canal. The roots of the molar teeth do not project up into it.

BONES OF THORACIC LIMB

The =clavicle= is a small, thin, irregularly-triangular bony or cartilaginous plate. It is embedded in the mastoido-humeralis muscle in front of the shoulder joint and forms no articulation with the rest of the skeleton. (It is nearly an inch long in a large cat and is a slender curved rod.)

[Illustration:

FIG. 128.—RIGHT SCAPULA OF DOG, EXTERNAL VIEW.

_a_. Supraspinous fossa; _b_, infraspinous fossa; _c_, spine; _d_, upper broad end of spine; _e_, acromion; _f_, glenoid cavity; _g_, tuberosity; _h_, vertebral border; _i_, posterior angle; _k_, scapular notch. (Ellenberger-Baum, Anat. d. Hundes.)]

[Illustration:

FIG. 129.—LEFT SCAPULA OF DOG, COSTAL SURFACE.

_a_, Subscapular fossa; _b_, _b_, _b_, muscular lines; _c_, _c_, limiting line between subscapular fossa and serratus area; _d_, glenoid cavity; _e_, _f_, tuberosity; _g_, nutrient foramen. (Ellenberger-Baum, Anat. d. Hundes.)]

The =scapula= is relatively long and narrow. The spine increases gradually in height from above downward and divides the external surface into two nearly equal fossæ. Its free edge is thick and rough above, and at the lower part is thin and bent backward. The =acromion= is short and blunt and is opposite the rim of the glenoid cavity. The subscapular fossa is very shallow and is marked by rough lines. The rough area above it for the attachment of the serratus magnus is large and quadrilateral in front, narrow and marginal behind. The anterior border is thin, strongly convex, and sinuous. The posterior border is straight and thick. The vertebral border is convex and thick and bears a band of cartilage. The cervical angle is rounded. The dorsal angle is thick and square. The neck is well defined and bears a rough eminence posteriorly. The glenoid cavity is continued forward upon the lower face of the scapular tuberosity, which is blunt and bears no distinct coracoid process. There is a rough eminence on the posterior surface of the neck, from which the long head of the triceps arises. The cervical angle is opposite the first thoracic spine, the dorsal angle lies above the vertebral end of the fourth rib, and the articular angle at a point just in front of the sternal end of the first rib in the ordinary standing position. The shoulder has a great range of movement on the chest-wall.

The =humerus= is relatively very long, rather slender, and has a slight spiral twist. The shaft is somewhat compressed laterally, especially in its upper two-thirds; this part is curved in varying degree, convex in front. The deltoid tuberosity has the form of a low ridge, and it is continued by a crest which runs upward and backward and bears a tubercle on its upper part. Another line runs from it down the anterior aspect and forms the inner boundary of the very shallow musculo-spiral groove. The nutrient foramen is about in the middle of the posterior surface. A slight elevation on the proximal third of the inner surface represents the teres tubercle. The head is long and strongly curved from before backward. The neck is better marked than in the horse. The undivided external tuberosity is placed well forward and extends little above the level of the head. The internal tuberosity is small. The bicipital groove is undivided and is displaced to the inner side by the extension forward of the external tuberosity. The distal end bears an oblique trochlear articular surface for articulation with the radius and ulna, the outer part of which is the more extensive and is faintly grooved. The epicondyles are prominent. The coronoid and olecranon fossæ often communicate through a large =supratrochlear foramen=.

[Illustration:

FIG. 130.—LEFT HUMERUS OF DOG, EXTERNAL VIEW.

_a_, Head; _b_, neck; _c_, crest; _d_, external tuberosity; _e_, mark for insertion of infraspinatus tendon; _f_, external condyle; _g_, external condyloid crest; _h_, coronoid fossa; _i_, olecranon fossa. (Ellenberger-Baum, Anat. d. Hundes.)]

[Illustration:

FIG. 131.—LEFT RADIUS AND ULNA OF DOG, ANTERO-EXTERNAL VIEW.

_A_, Radius; _B_, ulna; _a_, groove for tendon of extensor carpi radialis: _b_, groove for common extensor tendon; _c_, proximal articular surface of radius; _d_, olecranon; _e_, beak (proc. anconeus) of ulna; _f_, semilunar notch; _g_, coronoid process; _h_, facet for radius; _i_, groove for lateral extensor tendon; _k_, groove for tendon of extensor carpi obliquus. (Ellenberger-Baum, Anat. d. Hundes.)]

The two bones of the forearm are relatively long and articulate with each other at either end in such a manner as to allow of slight movement. A narrow interosseous space separates their shafts. The =radius= is flattened from before backward and increases in size from above downward. The shaft forms two curves; one of these, an anterior convexity, involves the whole shaft; the other, an inner convexity, affects the upper part. The anterior surface is convex in both directions and is marked by a groove for the oblique extensor of the carpus. The posterior surface presents the nutrient foramen in its upper third, and bears a rough line (Crista interossea) externally for the attachment of the interosseous ligament. The proximal end (Capitulum radii) is relatively small and is supported by a distinct neck (Collum radii). It bears a concave surface (Fovea capituli) above for articulation with the humerus, and a convex marginal area (Circumferentia articularis) behind for the ulna. The bicipital tuberosity is small. There is a large external tuberosity and below this a rough eminence. The distal extremity is much wider. It has an extensive concave carpal articular surface. Its inner border projects downward, forming the =styloid process= of the radius. Externally there is a concave facet (Incisura ulnaris radii) for the ulna. In front are three distinct grooves for the extensor tendons. The =ulna= is well developed, but diminishes in size from above downward. It crosses the posterior surface of the radius from within outward. The shaft is large and three-sided in its upper two-thirds, smaller and more rounded below. Its anterior surface is in general rough. The nutrient foramen is near the proximal end. A vascular groove descends from it and indicates the course of the interosseous artery. The proximal end is relatively short. It is concave and smooth internally, convex and rough externally. The olecranon is grooved and bears three prominences, of which the posterior one is large and rounded. The semilunar notch is wide below and completes the surface for articulation with the trochlea of the humerus. Below it is a concave surface (Incisura radialis) which articulates with the back of the head of the radius, and below this is a fossa, which receives a tuberosity of the radius. The distal end (Capitulum ulnæ) is small and is produced to a blunt point (Processus styloideus ulnæ). It articulates with the ulnar carpal below, and has a convex facet on its antero-internal aspect for the radius.

[Illustration:

FIG. 132.—SKELETON OF DISTAL PART OF THORACIC LIMB OF DOG, EXTERNAL VIEW.

_4_, Radial + intermediate carpal bone; _5_, ulnar carpal; _6_, accessory carpal; _7_, second carpal; _8_, third carpal; _9_, fourth carpal; _10–14_, first to fifth metacarpals; _15_, first phalanx; _16_, second phalanx; _17_, third phalanx. (After Leisering’s Atlas.)]

The =carpus= comprises seven bones, three in the proximal row and four in the distal. The numerical reduction in the upper row is apparently due to the fusion of the radial and intermediate, constituting a large bone which articulates with almost all of the distal surface of the radius and with the bones of the lower row. It projects prominently on the posterior surface of the carpus. The ulnar carpal is long; it articulates with the radius and ulna above and the accessory behind; below it rests on the fourth carpal and is prolonged downward to articulate with the fifth metacarpal also. The accessory is cylindrical, constricted in its middle and enlarged at each end; the anterior extremity articulates with the ulna and ulnar carpal bone. The first carpal is the smallest bone of the lower row; it articulates with the second carpal externally and the first metacarpal distally. The second carpal is wedge-shaped, the base being posterior; its upper surface is convex, and its lower is concave and rests on the second metacarpal. The third carpal is somewhat like the second; its lower surface is concave and articulates chiefly with the third metacarpal. The fourth carpal is the largest of the row; it articulates with the fourth and fifth metacarpals below. Two small bones or cartilages may be found at the junction of the two rows behind, and a third small bone articulates with the inner side of the radiointermediate.[27]

Five =metacarpal bones= are present. The first is much the shortest; the third and fourth are the longest, and are about one-fifth longer than the second and fifth. The fifth is the widest at the proximal end and is slightly shorter than the second. They are close together above, but diverge somewhat below; the first is separated from the second by a considerable interosseous space. They are so arranged as to form a convex dorsal surface, and a concave volar surface, which corresponds to the hollow of the palm of the hand in man. Each consists of a shaft and two extremities. The shaft is compressed from before backward. In the third and fourth it is almost four-sided, in the second and fifth three-sided, in the first rounded. The proximal ends (Bases) articulate with each other and with the corresponding carpal bones. The carpal articular surface formed by them is concave from side to side, convex from before backward. The distal ends (Capitula) have articular surfaces of the nature of a head, but bear a sagittal ridge behind, except the first, which is grooved.

[Illustration:]

FIG. 133.—SECOND AND THIRD PHALANGES OF DOG.

_a_, Wing of third phalanx; _b_, coronary ridge; _c_, foramen for digital artery; _d_, ungual surface of third phalanx; _e_, second phalanx; _f_, first phalanx; _g_, elastic dorsal ligaments. (From Leisering's Atlas.)]

The five =digits= have three phalanges each, except the first, which has two. The third and fourth digits are the longest; the first is very short and does not come in contact with the ground in walking. The =first phalanges= of the chief digits have four-sided shafts, which are slightly curved forward. The proximal end of each has a concave surface for articulation with the metacarpal bone and is deeply notched behind. The distal end has a trochlea for articulation with the second phalanx, and lateral depressions for ligamentous attachment. The =second phalanges= are about two-thirds of the length of the first phalanges. The proximal articular surface consists of two cavities separated by a sagittal ridge. The distal extremity is wider and flatter than that of the first. The =third phalanges= correspond in general to the form of the claws. The base has an articular surface adapted to the second phalanx and is encircled by a collar of bone. The volar surface bears a wing or tuberosity, and on either side of this is a foramen. The ungual part is a curved rod with a blunt-pointed free end. It is rough and porous. Its base forms with the collar previously mentioned a deep groove, into which the proximal border of the claw is received. The two phalanges of the first digit resemble in arrangement the first and third phalanges of the other digits.

Nine =volar sesamoids= are usually present. Two are found at each metacarpo-phalangeal joint of the chief digits. They are high and narrow, articulate with the distal end of the metacarpal bone in front, and have a small facet on the base for the first phalanx. On this joint of the first digit there is usually a single flattened sesamoid, but exceptionally two are present. The distal volar sesamoids remain cartilaginous. A nodular =dorsal sesamoid= occurs in the anterior part of the capsule of the metacarpo-phalangeal joints, and cartilaginous nodules are found in a similar position in connection with the joints between the first and second phalanges.

BONES OF THE PELVIC LIMB

The =ilium= is nearly parallel with the median plane and its axis is only slightly oblique with regard to the horizontal plane. The gluteal surface is concave. The iliac surface is almost flat. The auricular surface faces almost directly inward, and in front of it there is an extensive rough area. The ilio-pectineal line is very distinct and is uninterrupted. The anterior border or crest is strongly convex, thick, and rough. The internal angle is represented by a thickened part which bears two eminences, homologous with the posterior superior and posterior inferior iliac spines of man. The external angle also has two prominences, which are equivalent to the two anterior spines present in man. The shaft is almost sagittal and is compressed laterally. Above it is smooth and rounded, and below it bears a crest externally which terminates at a tuberosity in front of the acetabulum.

The =ischium= has a twisted appearance owing to the fact that its acetabular part is nearly sagittal while the posterior part is almost horizontal. The two bones also diverge behind and the tubera are flattened and everted. The superior ischiatic spine is low and thick; its posterior part is marked by transverse grooves and has a prominent outer lip. There is no lesser sciatic notch. The ischial arch is relatively small and is semi-elliptical.

[Illustration:]

FIG. 134.—OSSA COXARUM OF DOG, LEFT POSTERIOR VIEW.

_a_. Crest; _b_, _c_, internal angle; _d_, great sciatic notch; _e_, _f_, external angle; _g_, posterior gluteal line; _h_, gluteal fossa of wing; _i_, shaft of ilium; _k_, anterior gluteal line; _l_, auricular surface; _m_, ilio-pectineal line; _n_, depression for origin of rectus femoris; _o_, acetabulum; _p_, acetabular, and _q_, symphyseal branch of pubis; _r_, psoas tubercle; _s_, obturator foramen; _s′_, obturator notch; _t_, line for origin of coccygeus; _u_, superior ischiatic spine; _v_, external border of ischium; _w_, tuber ischii; _x_, ischial arch. (Ellenberger-Baum, Anat. d. Hundes.)]

[Illustration:]

FIG. 135.—LEFT FEMUR OF DOG, ANTERIOR VIEW.

_a_, Head; _b_, neck; _c_, trochanter major; _d_, trochanter minor; _e_, rudimentary trochanter tertius; _f_, rough line; _g_, trochlea; _h_, _i_, condyles; _k_, suprapatellar fossa. (Ellenberger-Baum, Anat. d. Hundes.)]

[Illustration:

FIG. 136.—LEFT TIBIA AND FIBULA OF DOG, ANTERO-EXTERNAL VIEW.

_A_, Tibia; _B_, fibula; _a_, external condyle of tibia; _b_, spine; _c_, crest of tibia; _d_, muscular notch; _e_, internal malleolus; _f_, head of fibula; _g_, interosseous space; _h_, external malleolus (distal end of fibula); _i_, groove for tendon. (Ellenberger-Baum, Anat. d. Hundes.)]

The symphyseal part of the =pubis= is thick and fuses late with the opposite bone. There is no subpubic groove.

The =acetabulum= is about twice as far from the external angle of the ilium as from the tuber ischii. The fossa acetabuli is deep, and is bounded internally by a flat plate of bone; its floor is so thin as to be translucent. There is a small notch behind.

The =obturator foramen= resembles in outline an equilateral triangle with the angles rounded off.

[Illustration:

FIG. 137.—SKELETON OF DISTAL PART OF PELVIC LIMB OF DOG, EXTERNAL VIEW.

_6_, Tibial tarsal bone; _7_, fibular tarsal; _8_, central tarsal; _9_, second tarsal; _10_, third tarsal; _11_, fourth tarsal; _12_, metatarsal bones; _13_, first phalanx. The first tarsal bone is not visible in the figure. (After Leisering's Atlas.)]

The inlet of the =pelvis= is very oblique. It is almost circular in the female, but in the male it is elliptical and the conjugate diameter is the longer. The cavity is narrowest between the acetabula, and very wide behind. The floor is concave and relatively narrow in front, wide and flat behind.

The =femur= is relatively much longer than in the horse or ox. The shaft is regularly cylindrical, except near the extremities, where it is wider and compressed from before backward. It is strongly curved in its lower two-thirds, convex in front. The posterior surface is flattened transversely, narrow in the middle, and widens toward each end. It is bounded by two rough lines (Labium laterale, mediale) which diverge toward the extremities. The third trochanter and the plantar (supracondyloid) fossa are absent. There are two supracondyloid crests, the inner one being small. The nutrient foramen is in the upper third of the posterior surface. The head is a little more than a hemisphere and has a shallow depression behind and external to its center. The neck is well defined. The trochanter major does not extend as high as the head; a thick ridge runs from its anterior surface to the neck. The internal trochanter has the form of a blunt tuberosity. The trochanteric fossa is round and deep. The ridges of the trochlea are practically sagittal in direction and are almost similar. The intercondyloid fossa is wide. Just above each condyle posteriorly there is a facet for articulation with the sesamoid (of Vesal), which is developed in the origin of the gastrocnemius muscle.

The =tibia= is about the same length as the femur. The shaft forms a double curve; the upper part is convex internally, the lower part externally. The proximal third is prismatic, but is compressed laterally and is long from before backward. The remainder is almost regularly cylindrical. The crest is short but very prominent. The nutrient foramen is usually in the upper third of the external border. The tuberosity is not grooved, but bears a distinct mark where the ligamentum patellæ is attached. There is a small facet for the fibula on the postero-external part of the external condyle, and a small sesamoid bone in the tendon of origin of the popliteus is in contact with the posterior angle of the latter. The distal end is quadrangular and relatively small. The articular grooves and ridge are almost sagittal. There is a facet externally for articulation with the fibula. There is a vertical groove internally and a shallower one behind—both for tendons.

The =fibula= extends the entire length of the region. It is slender, somewhat twisted, and enlarged at either end. The upper part of the shaft is separated from the tibia by a considerable interosseous space, but the lower part is flattened and closely applied to the tibia. The proximal end is flattened and articulates with the external condyle of the tibia. The distal end is somewhat thicker and forms the external malleolus. It articulates internally with the tibia and the tibial tarsal bone. Externally it bears two tubercles.

The =patella= is long and narrow. The anterior surface is convex in both directions. The articular surface is convex from side to side and slightly concave from above downward.

The =tarsus= comprises seven bones. The tibial tarsal consists of a body, neck, and head, like the bone in man. The body presents a trochlea above for articulation with the tibia and fibula. The posterior surface has three facets for articulation with the fibular tarsal bone. The head is directed a little inward and articulates with the central. The fibular tarsal has a long anterior process or "beak,"

but the inner process (sustentaculum) is short. The tuber calcis is grooved from before backward. The central has a concave proximal surface adapted to the head of the tibial tarsal. Its distal surface articulates with the first, second, and third tarsals. It bears two tubercles posteriorly. The first tarsal is flattened and irregularly quadrangular; it articulates above with the central and below with the first metatarsal. The second tarsal is the smallest and is wedge-shaped; it articulates below with the second metatarsal bone. The third tarsal is also wedge-shaped, the base being in front; it articulates with the third metatarsal below. The fourth tarsal is remarkably high, and resembles a quadrangular prism; it articulates with the fibular tarsal above, the fourth and fifth metatarsal below, and the central and third tarsal bones internally. A groove for the tendon of the peroneus longus crosses its outer and posterior surface, and above it are one or two tubercles.

Five =metatarsal bones= are present. The first is commonly very small and has the form of a blunt cone, somewhat compressed laterally. It articulates with the first tarsal and furnishes insertion to the tibialis anterior muscle. In some cases it fuses with the first tarsal; when the first digit is well developed, its metatarsal may resemble the others (except in size) or be reduced in its proximal part to a fibrous band. The other metatarsals are a little longer than the corresponding metacarpals. Their proximal ends are elongated from before backward and have posterior projections, which in the case of the third and fourth usually bear facets for articulation with two small rounded sesamoid bones. In other respects they resemble the metacarpals.

The first digit is often absent. When present, its development varies and it contains one or two phalanges. In other cases the digit is double. The phalanges of the other digits resemble those of the fore limb.

ARTHROLOGY

THE ARTICULATIONS OR JOINTS

An =articulation= or =joint= is formed by the union of two or more bones or cartilages by other tissue. Bone is the fundamental part of most joints; in some cases a bone and a cartilage, or two cartilages, form a joint. The uniting medium is chiefly fibrous tissue or cartilage, or a mixture of these. Union of parts of the skeleton by muscles (Synsarcosis), as in the attachment of the thoracic limb in the horse, will not be considered in this section.

Joints may be classified—(_a_) anatomically, according to their mode of development, the nature of the uniting media, and the form of the joint surfaces; (_b_) physiologically, with regard to the amount and kind of movement or the absence of mobility in them; (_c_) by a combination of the foregoing considerations.

The classification of joints is still in a very unsatisfactory state, and, unfortunately, the same term is used in various senses by different authors. The two main subdivisions proposed by Hepburn are: (1) Those in which the uniting medium is coextensive with the opposed joint surfaces, and in which a direct union of these surfaces is thereby effected. (2) Those in which the uniting medium has undergone interruption in its structural continuity, and in which a cavity of greater or less extent is thus formed in the interior of the joint. This distinction is of considerable importance clinically.

Three chief subdivisions of joints are usually recognized—viz., =synarthroses=, =diarthroses=, and =amphiarthroses=.

SYNARTHROSES

In this group the segments are united by fibrous tissue or cartilage, or a mixture of the two in such a manner as practically to preclude movement; hence they are often termed fixed or immovable joints. There is no joint cavity. Many of these joints are temporary, the uniting medium being invaded by the process of ossification, with a resulting ankylosis or synostosis. The chief classes in this group of joints are as follows:

(1) =Suture.=—This term (Sutura) is applied to those joints in the skull in which the adjacent bones are closely united by fibrous tissue—the sutural ligament. In many cases the edges of the bones have irregular interlocking margins, forming the =sutura serrata=, _e. g._, the frontal suture. In others the edges are beveled and overlap, forming the =sutura squamosa=, _e. g._, the parieto-temporal suture. If the edges are plane or slightly roughened, the term =sutura harmonia= is applied to the joint, _e. g._, the nasal suture.

(2) =Synchondrosis.=—In these the two bones are united by cartilage, _e. g._, the joint between the basioccipital and the sphenoid bone. Very few of these joints are permanent.

(3) =Symphysis.=—This term is usually limited to a few median joints which connect symmetrical parts of the skeleton, _e. g._, symphysis pelvis, symphysis mandibulæ. The uniting media are cartilage and fibrous tissue. In some cases a cleft-like rudimentary joint cavity occurs.

(4) =Gomphosis.=—This term is applied to the implantation of the teeth in the alveoli.

DIARTHROSES

These joints are characterized by the presence of a joint cavity and by their mobility. They are often called movable or true joints. The structures which enter into their formation are:

1. The =joint surfaces= (Facies articulares), which are usually more or less expanded. They are in most cases smooth, and vary much in form. They are formed of specially dense bone, which differs histologically from ordinary compact substance. In certain cases (_vide_ Osteology) the surface is interrupted by non-articular cavities known as =synovial fossæ=.

2. The =articular cartilages= (Cartilagines articulares), usually hyaline in type, form a covering over the articular surfaces of the bones. They vary in thickness in different joints; they are thickest on the areas of the greatest pressure, and usually tend to accentuate the curvature of the bone, _i. e._, on a concave surface the peripheral part is the thickest, while on a convex surface the central part is the thickest. The articular cartilages are non-vascular, very smooth, and have a bluish tinge in the fresh state. They diminish the effects of concussion and greatly reduce friction.

[Illustration:

FIG. 138.—DIAGRAM OF SECTION OF DIARTHROSIS.

_f.l._, Fibrous layer, _s.l._, synovial layer of joint capsule. The articular cartilages are white, bones dotted, and the joint cavity black in the figure.]

3. The =joint capsule= (Capsula articularis) is, in its simplest form, a sac, the margins of which are attached around the articulating surfaces. It consists of two layers—an external one, composed of fibrous tissue (Stratum fibrosum), and an internal one, the synovial layer or membrane (Stratum synoviale). The =fibrous layer=, sometimes termed the capsular ligament, is attached either close to the margins of the articular surfaces or at a variable distance from them. Its thickness varies greatly in different situations: in certain places it is extremely thick, and sometimes cartilage or bone develops in it; in other places it is practically absent, the capsule then consisting only of the synovial membrane. Parts of the capsule may undergo thickening and so form ligaments, which are not separable, except artificially, from the rest of the capsule. The =synovial layer= lines the joint cavity except where this is bounded by the articular cartilages; it stops normally at the margin of the latter. It is a thin membrane, and is richly supplied by close networks of vessels and nerves. It frequently forms =folds= (Plicæ synoviales) and =villi= (Villi synoviales), which project into the cavity of the joint. The folds commonly contain pads of fat which fill up interstices and vary in form and position in various phases of movement. The synovial membrane secretes a fluid, the =synovia=, which resembles white-of-egg and lubricates the joint.[28] In many places the membrane forms extra-articular pouches, which facilitate the play of muscles and tendons.

The =joint cavity= (Cavum articulare) is inclosed by the synovial membrane and the articular cartilages. Normally, it is, strictly speaking, only a potential cavity, which contains nothing but a small amount of synovia.

The student must guard against a false conception of the joint cavity which may result from dissections and diagrams, in which an actual cavity of considerable extent appears to exist. A correct idea of the intimate apposition of the parts is best obtained from the study of frozen sections. It is also instructive to examine joints which have been injected so as to distend the capsule fully. It is then seen that the cavity is often of much greater potential extent than one might suppose, and that the capsule is often very irregular in form, _i. e._, forms a variety of sacculations.

The foregoing are constant and necessary features in all diarthroses. Other structures which enter into the formation of these joints are ligaments, articular discs or menisci, and marginal cartilages.

4. =Ligaments.=—These are strong bands or membranes, usually composed of white, fibrous tissue, which bind the bones together. They are pliable, but practically inelastic. In a few cases, however, _e. g._, ligamenta flava, ligamentum nuchæ, they are composed of elastic tissue. They may be subdivided, according to position, into =periarticular= and =intraarticular=. Periarticular ligaments are frequently blended with or form part of the fibrous capsule; in other cases they are quite distinct. Strictly speaking,

intraarticular ligaments, though within the fibrous capsule, are not in the joint cavity; the synovial membrane is reflected over them. The term seems justifiable, however, on practical grounds. Ligaments which connect directly opposed surfaces of bones are termed interosseous. The special names are based usually on their position, form, and attachments, _e. g._, lateral or collateral, cruciate, sacro-iliac, etc. In many places muscles, tendons, and thickenings of the fasciæ function as ligaments and increase the security of the joint. Atmospheric pressure and cohesion play a considerable part in keeping the joint surfaces in apposition.

5. =Articular discs= or =menisci= are plates of fibro-cartilage or dense fibrous tissue placed between the articular cartilages, and divide the joint cavity partially or completely into two compartments. They render certain surfaces congruent, _e. g._, femoro-tibial joint, allow greater range or variety of movement, and diminish concussion.

6. A =marginal cartilage= (Labrum glenoidale) is a ring of fibro-cartilage which encircles the rim of an articular cavity. It enlarges the cavity and tends to prevent fracture of the margin.

=Vessels and Nerves.=—The =arteries= form anastomoses around the larger joints, and give off branches to the extremities of the bones and to the joint capsule. The synovial membrane has a close-meshed network of capillaries; the latter form loops around the margins of the articular cartilages, but do not usually enter them. The =veins= form plexuses. The synovial membrane is also well supplied with lymphatics. Nerve-fibers are especially numerous in and around the synovial membrane and there are special nerve-endings, _e. g._, Pacinian bodies and the articular end-bulbs described by Krause.

=Movements.=—The movements of a joint are determined chiefly by the form and extent of the joint surfaces and the arrangement of the ligaments. They are usually classified as follows:

1. =Gliding.=—This refers to the sliding of one practically plane surface on another, as in the joints between the articular processes of the cervical vertebræ.

2. =Angular Movements.=—In these cases there is movement around one or more axes. Motion which diminishes the angle included by the segments forming the joint is termed =flexion=, while that which tends to bring the segments into line with each other is called =extension=.

With reference to the joints of the lower parts of the limbs, it seems advisable to employ the terms =dorsal= and volar or =plantar flexion=, since these joints can be “overextended.” Similarly, the terms =dorsal= and =ventral flexion= should be applied to the corresponding movements of the spinal column. The meaning of the term =lateral flexion= is evident. These movements are all rotations around axes which are approximately either transverse or vertical. Depression, elevation, and lateral movement of the lower jaw fall in this category.

3. =Circumduction.=—This designates movements in which the distal part of the limb describes a circle or a segment of one. In man such movement is easily performed, but in quadrupeds it is possible to a limited degree only, and is to be regarded usually as an indication of disease.

4. =Rotation.=—As a matter of convenience, this term is reserved to indicate rotation of one segment around the longitudinal axis of the other segment forming the joint. It is seen typically in the atlanto-axial joint.

5. =Adduction= and =abduction= designate respectively movement of a limb toward and away from the median plane, or of a digit toward and away from the axis of the limb.

=Classification.=—This is based on the form of the joint surfaces and the movements which occur. The following chief classes may be recognized:

1. =Arthrodia=, or gliding joint. In these the surfaces are practically flat, admitting of gliding movement. Examples: carpo-metacarpal joints; joints between the articular processes of the cervical and thoracic vertebræ.

2. =Ginglymus=, or hinge-joint. In this class the joint surfaces consist usually of two condyles, or of a segment of a cylinder or cone, which are received by corresponding cavities. In typical cases the movements are flexion and extension, _i. e._, around a single transverse axis. Examples: occipito-atlantal and elbow joints.

3. =Trochoid=, or pivot joint. In these the movement is limited to rotation of one segment around the longitudinal axis of the other. Example: atlanto-axial joint.

4. =Enarthrosis=, or ball-and-socket joint. These are formed by a surface of approximately spherical curvature, received into a corresponding cavity. They are multiaxial, and allow of the greatest variety of movement, _e. g._, flexion, extension, rotation, abduction, adduction, circumduction. Examples: hip and shoulder joints.[29]

AMPHIARTHROSES

These joints, as the name indicates, share some characters with both of the preceding groups. In them the segments are directly united by a plate of fibro-cartilage, and usually by ligaments also. The amount and kind of movement are determined by the shape of the joint surfaces and the amount and pliability of the uniting medium.[30] These joints are all medial in position, and are best illustrated by the joints between the bodies of the vertebræ. There is usually no joint cavity, but in certain situations a rudimentary one exists.

THE ARTICULATIONS OF THE HORSE

JOINTS AND LIGAMENTS OF THE VERTEBRÆ

The movable vertebræ form two sets of articulations, viz., those formed by the bodies, and those formed by the articular processes of adjacent vertebræ; the former are termed =intercentral=, and the latter, =interneural=. Associated with these are ligaments uniting the arches and processes; some of these are =special=, _i. e._, confined to a single joint, while others are =common=, _i. e._, extend along the entire vertebral column or a considerable part of it. The joints between the atlas and axis and between the former and the skull require separate consideration.

INTERCENTRAL ARTICULATIONS

These are =amphiarthroses=, formed by the junction of the extremities of the bodies of adjacent vertebræ. The =articular surfaces= in the cervical region consist of a cavity on the posterior end of the body of the anterior vertebra, and a corresponding convexity or head of the succeeding vertebra. In the other regions the surfaces are much flattened. The uniting media are:

1. The =intervertebralfibro-cartilages= (Fibrocartilagines intervertebrales). Each of these is a disc which fits into the space between the bodies of two adjacent vertebræ, to which it is intimately attached. The discs are thinnest in the middle of the thoracic region, thicker in the cervical and lumbar regions, and thickest in the coccygeal region. Each consists of a dense fibrous peripheral part (Annulus fibrosus), and a soft pulpy central part (Nucleus pulposus).

[Illustration:

FIG. 139.—SAGITTAL SECTION OF LAST TWO THORACIC AND FIRST LUMBAR VERTEBRÆ, SHOWING LIGAMENTS AND SPINAL CORD (MEDULLA). (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The fibrous ring consists of laminæ of fibrous tissue and fibro-cartilage, which pass obliquely between the two vertebræ and alternate in direction, forming an X-shaped arrangement. The central part of the ring is largely cartilaginous, and gradually assumes the character of the pulpy center. The latter is very elastic and is compressed, so that it bulges considerably from the surface of sections; it consists of white and elastic fibers, connective-tissue cells, and peculiar clear, transparent cells of various sizes. It is a remnant of the notochord. There are joint cavities in the cervical intercentral joints, and in those between the last cervical and the first thoracic, and between the last lumbar and the sacrum. In the latter the cavity is coextensive with the extremities of the bodies; in the former, it is usually not so extensive.

2. The =inferior common ligament= (Ligamentum longitudinale ventrale) lies on the ventral surface of the bodies of the vertebræ and the intervertebral fibro-cartilages, to which it is firmly attached. It begins about the fourteenth or fifteenth thoracic vertebra, and is at first a narrow, thin band. Further back it becomes gradually thicker and wider, and terminates on the pelvic surface of the sacrum by spreading out and blending with the periosteum. It is strongest in the lumbar region, where the tendons of the crura of the diaphragm fuse with it.

3. The =superior common ligament= (Ligamentum longitudinale dorsale) lies on the floor of the vertebral canal from the dens or odontoid process to the sacrum. It is narrow over the middles of the vertebral bodies, and widens over the intervertebral fibro-cartilages, to which it is very firmly attached.

This ligament is in relation with the spinal veins on either side, and in the middle of each vertebra a transverse anastomotic branch passes under the ligament.

INTERNEURAL ARTICULATIONS

Each typical vertebra presents two pairs of articular processes, which form diarthroses with the two adjacent vertebræ. The =articular surfaces= are extensive, flat, and oval in the cervical region, small and flat in the thoracic region, while in the lumbar region the anterior ones are concave and the posterior convex. The joint capsule is strong and ample in the cervical region, in conformity with the large size and greater mobility of these joints in the neck. In the thoracic and lumbar regions the capsule is small and close. These joints are arthrodia.

Associated with these joints are the =ligamenta flava=, which connect the arches of adjacent vertebræ. They are membranous and consist largely of elastic tissue.

[Illustration:

FIG. 140.—LIGAMENTUM NUCHÆ OF HORSE.

_1_, Scapula; _1′_, cartilage of scapula; _4_, lamellar part of ligamentum nuchæ; _x_, wing of atlas. (After Ellenberger-Baum, Anat. für Künstler.)]

The =supraspinous ligament= extends medially from the occipital bone to the sacrum. From the withers backward it consists of a strong cord of fibrous tissue, attached to the summits of the vertebral spines. In the neck and withers it is remarkably modified to form the ligamentum nuchæ, which requires more extended notice.

The =ligamentum nuchæ= is a powerful elastic apparatus, the principal function of which is to assist the extensor muscles of the head and neck. It extends from the occipital bone to the withers, where it is directly continuous with the supraspinous ligament. It consists of two parts—funicular and lamellar. The =funicular part= (Pars occipitalis) arises from the external occipital protuberance and the fossa below it, and is inserted into the summits of the vertebral spines at the withers. Two =bursæ= are usually found under it in the adult. The =supra-atloid bursa= lies between the ligament and the dorsal arch of the atlas. The =supraspinous bursa= occurs usually over the fourth thoracic spine, but may be over the third and may extend to the fifth.[31] In the neck the funicular part consists for the greater part of two bands closely applied and attached to each other. Near and at the withers it broadens greatly, forming an expansion three to five inches (ca. 8 to 12.5 cm.) in width, the lateral margins of which are thin and overlie the trapezius and rhomboideus muscles. Behind the higher spines it becomes narrower and thinner, and is continued by the white fibrous lumbo-dorsal ligament.[32] A mass of fat and elastic tissue lies upon the ligament as far back as the withers. It varies greatly in amount in different subjects, and is most developed in stallions of draft breeds, in which it forms the basis of the “crest.” The =lamellar portion= (Pars cervicalis) consists of two laminæ separated medially by a layer of loose connective tissue. Each lamina is formed of digitations which arise from the second and third thoracic spines and from the funicular portion, are directed downward and forward, and end on the spines of the cervical vertebræ, except the first and last. The digitation which is attached to the spine of the axis is very thick and strong. Behind this they diminish in size and strength; that to the sixth cervical is quite thin and feeble, or may be absent.

The =interspinous ligaments= (Ligamenta interspinalia) extend between the spines of contiguous vertebræ. In the cervical region they are narrow elastic bands, and in the thoracic and lumbar regions they consist of white fibers directed obliquely downward and forward.

The =intertransverse ligaments= (Ligamenta intertransversaria) are membranes which connect adjacent transverse processes in the lumbar region.

INTERTRANSVERSE ARTICULATIONS

These joints (peculiar to equidæ) are diarthroses formed by the transverse processes of the last two lumbar vertebræ and the alæ of the sacrum. A similar joint between the fourth and fifth lumbar processes is frequently present. The =articular surfaces= have an elongated oval form, the anterior one being concave and the posterior one convex. The capsule is tight, and is reinforced ventrally.

SACRAL AND COCCYGEAL ARTICULATIONS

In the foal the bodies of the five sacral vertebræ form joints which resemble somewhat those in the posterior part of the lumbar region. These joints are invaded by the process of ossification early, so that the consolidation of the sacrum is usually complete, or nearly so, at three years.

The coccygeal vertebræ are united by relatively thick intervertebral fibro-cartilages, which have the form of biconcave discs. Special ligaments are not present, but there is a continuous sheath of fibrous tissue. The movement in this region is extensive and varied. In old horses the first coccygeal vertebra is often fused with the sacrum.

MOVEMENTS OF THE VERTEBRAL COLUMN

The movements of the spine, exclusive of those at the atlanto-axial joint, are dorsal, ventral, and lateral flexion, and rotation. The range of movement at a single joint is very small, but the sum of the movements is considerable. The movements are freest in the cervical and coccygeal regions. Rotation is extremely limited in the thoracic and lumbar regions.

ATLANTO-AXIAL ARTICULATION

This is a trochoid or pivot joint, of a rather peculiar character. The articular surfaces are: (1) On the lateral masses of the atlas, two somewhat saddle-shaped facets, which are usually confluent ventrally; (2) on the axis, reciprocal saddle-shaped surfaces which extend upon the odontoid process and are confluent on its ventral aspect. It will be observed that the joint surfaces are not at all accurately adapted to each other, so that only limited areas are in contact at any time.

The =joint capsule= is attached around the margins of the articular surfaces. It is loose and ample enough laterally to allow extensive movement.

The =superior atlanto-axial ligament= (Ligamentum interarcuale) is membranous and reinforces the capsule dorsally.

The =interspinous ligament= (Ligamentum inter-spinale) consists of two elastic bands which extend from the dorsal arch of the atlas to the spine of the axis.

The =inferior atlanto-axial ligament= (Ligamentum dentis externum) arises from the ventral tubercle of the atlas and is attached by two branches on the ventral spine of the axis.

The =odontoid ligament= (Ligamentum dentis internum) is short, very strong, and somewhat fan-shaped. It extends from the rough concave dorsal surface of the dens or odontoid process, widens in front, and is attached to the transverse rough area on the inner surface of the ventral arch of the atlas.

=Movements.=—The atlas and the head rotate upon the axis; the axis of rotation passes through the center of the odontoid process and body of the axis.

[Illustration:

FIG. 141.—ATLANTO-OCCIPITAL AND ATLANTO-AXIAL JOINTS OF HORSE, DORSAL VIEW AFTER REMOVAL OF DORSAL ARCH OF ATLAS.

(Ellenberger-Baum, Anat. d. Haustiere.)]

THE ATLANTO-OCCIPITAL ARTICULATION

This joint may be classed as a ginglymus. The =articular surfaces= of this joint are: (1) On the atlas, two deep oval cavities; (2) the corresponding condyles of the occipital bone.

The joint surfaces are oblique, coming very close to the median line ventrally, but separated by a considerable interval dorsally. Posteriorly, a triangular rough area cuts into the middle of each articular surface on the atlas.

There are two roomy =joint capsules=, which sometimes communicate ventrally, especially in old subjects.

The =superior atlanto-occipital membrane= extends from the dorsal arch of the atlas to the upper margin of the foramen magnum. It is blended with the capsules and contains many elastic fibers.

The =inferior atlanto-occipital membrane= extends from the ventral arch of the atlas to the lower margin of the foramen magnum. It is narrower and thinner than the superior membrane, and also fuses with the joint capsules.

The =lateral ligaments= are two short bands which are partially blended with the capsules. Each is attached to the border of the wing of the atlas near the intervertebral foramen, and to the outer surface of the paramastoid or styloid process of the occipital bone.

=Movements.=—These are chiefly flexion and extension. A small amount of lateral oblique movement is also possible.

ARTICULATIONS OF THE THORAX

COSTO-VERTEBRAL ARTICULATIONS

Each typical rib forms two joints with the vertebral column, one by its head, and one by its tubercle. They are termed respectively costo-central and costo-transverse joints.

[Illustration:

FIG. 142.—COSTO-VERTEBRAL ARTICULATION, ANTERIOR VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

I. The =costo-central articulations= (Articulationes capitulorum) are trochoid or rotatory joints, formed by the junction of the head of the rib with the bodies of two adjacent vertebræ and the intervertebral fibro-cartilage. The two facets on the head of the rib are separated by a non-articular groove, and correspond to the two concave facets (Foveæ costales) on the vertebral bodies. The capsules are rather tight, and are covered by the accessory ligaments, which are as follows: 1. The =radiate ligament= (Ligamentum capituli costæ radiatum) extends ventrally from the neck of the rib to spread out on the vertebral bodies and the intervertebral fibro-cartilage. 2. The =conjugal ligament= (Ligamentum conjugale)—absent from the first joint—is attached to the groove on the head of the rib, passes transversely into the vertebral canal, and divides under the superior common ligament into two branches; one of these is attached to the body of the anterior vertebra; the other is continued across to the head of the opposite rib, and is attached to the intervertebral fibro-cartilage. The joint cavity is divided into two compartments by the conjugal ligament. 3. The =ligament of the neck= of the rib (Ligamentum colli costæ) is a strong band which crosses the joint dorsally. It is attached on the vertebra above the costal facet and on the neck of the rib.

II. The =costo-transverse articulations=. These occur between the facets on the tubercles of the ribs and those on the transverse processes of the vertebræ. They are gliding joints. The =capsule= is reinforced by the =superior costo-transverse ligament= (Ligamentum costo-transversarium dorsale), a distinct strong band which arises on the transverse process and ends on the non-articular part of the tubercle. It is covered by the levator costæ muscle, and begins to be quite distinct at the fifth joint.

The cavity for the head of the first rib is formed by concave facets on the bodies of the last cervical and first thoracic vertebræ. The conjugal ligament is absent, but the ligament of the neck is short and strong. The radiate ligament is very strong, and consists of two bands. In the case of the last two or three ribs the costo-central and costo-transverse joints are confluent, and the various structures are correspondingly modified.

=Movements.=—The chief movement is rotation around an axis which connects the centers of the head and tubercle of the rib. The movement is very limited in the anterior part of the series of joints, but very considerable in the posterior part.

In the case of the first rib, the movement is evidently extremely limited. The facet for the tubercle of the rib is deeply concave, and the axis of rotation is almost transverse. Further back the facets on the transverse processes become flat, and the axis of rotation gradually approaches a longitudinal direction. This, in connection with the mobility of the ventral ends of the asternal ribs and their elasticity, allows a great increase here in the range of movement, the effect of which is to enlarge (chiefly) the transverse diameter of the thorax.

COSTO-CHONDRAL ARTICULATIONS

The costo-chondral junctions are synarthroses. The rib has a concave surface which receives the convex end of the cartilage. They are united by the continuity of the strong periosteum and perichondrium.

CHONDRO-STERNAL ARTICULATIONS

These joints (Articulationes sternocostales) are diarthroses formed by the junction of the cartilages of the sternal ribs with the sternum. The articular ends of the cartilages (except the first) are somewhat enlarged, and present surfaces of cylindrical curvature. The articular surfaces on the sternum for the first pair of cartilages are placed close together on the dorsal border of the cariniform cartilage (Manubrium sterni); the other seven are placed laterally at the junction of the segments. The capsules are strong and tight; the first pair of joints has a common capsule, and the cartilages articulate with each other medially. The lower ends of the first pair of ribs are firmly attached to each other by dense fibrous tissue, which is prolonged forward along the upper margin of the cariniform cartilage and is continuous behind with the sternal ligament. Each of the other capsules is reinforced dorsally by the =superior costo-sternal ligament= (Ligamentum sternocostale radiatum), composed of radiating fibers which blend with the sternal ligament. The movement is rotation around a nearly vertical axis, except in the case of the first pair of joints.

INTERCHONDRAL LIGAMENTS

The eighth and ninth costal cartilages are firmly united by fibrous tissue. The chondro-xiphoid ligament attaches the ninth costal cartilage to the xiphoid cartilage. The remaining cartilages are rather loosely attached to each other by elastic tissue.

STERNAL ARTICULATIONS

In the new-born foal the sternum has seven bony segments (Sternebræ), united by persisting cartilage. The last two segments coalesce within a few weeks after birth. In old subjects there is more or less ossification of the intersegmental cartilage, which may lead to partial fusion of adjacent segments, especially posteriorly. The =sternal ligament= (Ligamentum sterni proprium internum) lies on the thoracic surface of the sternum. It arises on the first segment, and divides opposite the second chondro-sternal joint into three bands. The median band passes backward and spreads out on the last segment and the xiphoid cartilage. The lateral branches—thicker and wider—lie along the lateral borders above the chondro-sternal joints, and end at the cartilage of the eighth rib; they are covered by the transversus thoracis muscle.

THE ARTICULATIONS OF THE SKULL

TEMPORO-MANDIBULAR ARTICULATION

This joint (Articulatio mandibularis) is the only diarthrosis formed between bones of the skull.

The =articular surfaces= are dissimilar in form and size. That on the squamous temporal bone is concavo-convex, and the long axis is directed outward and somewhat forward; it consists of a glenoid cavity, which is continued upon the postglenoid process behind, and a condyle in front. The mandible presents a transversely elongated condyle.

The =articular disc= is placed between the joint surfaces, which it renders congruent. Its upper and lower surfaces are molded upon the temporal and mandibular surfaces respectively, and its circumference is attached to the joint capsule; thus it divides the joint cavity into upper and lower compartments, the former being the more roomy.

The =joint capsule= is strong and tight. It is reinforced by two ligaments. The =external ligament= (Ligamentum laterale) extends obliquely across the anterior part of the outer surface of the capsule, from which it is not distinctly separable. The =posterior ligament= (Ligamentum posterius) is an elastic band which is attached above to the postglenoid process, and below to a line on the posterior face of the neck of the mandible.

=Movements.=—The chief movements take place around a transverse axis passing through both joints. Associated with this hinge-like action is slight gliding movement, as in opening and shutting the mouth. When the mouth is shut, the condyle lies under the glenoid cavity. When the mandible is depressed, the condyle moves forward under the articular eminence of the temporal bone, carrying the disc with it. In protrusion and retraction of the lower jaw the gliding movement just described occurs without the hinge-like rotation of the condyle. These movements are similar in both joints. In the lateral movements (as usually performed in mastication) the action consists of rotation of the condyles around a vertical axis, while the disc glides forward on one side and backward on the other.

THE SYNARTHROSES OF THE SKULL

Most of the bones of the skull are united with the adjacent bones by =sutures=; a few are united by cartilage. The difference in the uniting medium depends on the fact that most of these bones are developed in membrane, but some are preformed in cartilage. Most of these joints are temporary, and are obliterated at various periods during development and growth. Their importance rests on the fact that so long as they persist, continuous growth is possible. They are usually designated according to the bones which enter into their formation, _e. g._, spheno-squamous, naso-frontal, internasal, etc. Special names (borrowed from human anatomy) are sometimes used; thus the interparietal, the parieto-occipital, and the parieto-frontal sutures are often called the sagittal, lambdoid, and coronal respectively.

Detailed description of the sutures has not sufficient clinical value to justify much addition to the statements made in the osteology in this connection. The obliteration or closure of the sutures is, however, worthy of brief mention. The cranial sutures are usually all closed at seven years, but the apex only of the petrous temporal is fused with the occipital and squamous temporal. Most of the facial sutures are practically closed at ten years, although complete synostosis may in some be delayed for years or may not occur at all; the nasal suture, for example, often persists even in advanced age, so far as its anterior part is concerned.

The principal =synchondroses= are: (1) That between the basioccipital and the body of the sphenoid (Synchondrosis sphenooccipitalis); (2) that between the presphenoid and postsphenoid (Synchondrosis intersphenoidalis); (3) those between the parts of the occipital bone (Synchondroses intraoccipitales). The first is usually ossified at four years, the second at three years, and the occipital bone is consolidated at two years.

The =symphysis= of the lower jaw (Symphysis mandibulæ) ossifies at one to six months.

THE HYOIDEAN ARTICULATIONS

The =temporo-hyoid articulation= is an amphiarthrosis, in which the dorsal angle of the proximal end of the great cornu (Stylo-hyal) is attached by a short bar of cartilage to the hyoid process of the petrous temporal bone. The cartilage (Arthrohyal) is about half an inch (ca. 1 to 1.5 cm.) in length. The chief movement is hinge-like, the axis of motion passing transversely through both joints.

The =intercornual articulation= is an amphiarthrosis formed by the junction of the distal extremity of the great cornu with the proximal end of the small cornu (kerato-hyal). They are united by a very short piece of cartilage, in which there is usually a small nodule of bone in the young subject. This nodule, the epihyal or middle cornu, is usually fused with the great cornu in the adult. The chief movement here is also hinge-like, the angle between the cornua being increased or diminished.

The =basi-cornual articulation= is a diarthrosis formed by the junction of each small cornu (kerato-hyal) with the body (basi-hyal). The small cornu has a concave facet which articulates with the convex facet on either end of the dorsal surface of the body. The capsule is ample enough to allow considerable movement, which is chiefly hinge-like. The movements of the hyoid bone are concerned chiefly in the acts of mastication and swallowing. In the latter the distal parts of the hyoid bone are moved forward and upward, carrying the root of the tongue and the larynx with them, and then return to their former position.

THE ARTICULATIONS OF THE THORACIC LIMB

In the absence of the clavicle the thoracic limb forms no articulation with the trunk, unless we regard as such the union by muscles. The movement of the shoulder on the chest-wall is chiefly rotation around a transverse axis passing through the scapula behind the upper part of the spine.

THE SHOULDER JOINT

The shoulder or scapulo-humeral joint (Articulatio scapulo-humeralis) is formed by the junction of the distal end of the scapula with the proximal end of the humerus. The =articular surfaces= are: (1) On the scapula, the glenoid cavity; (2) on the humerus, the head. Both surfaces are approximately spherical and similar in curvature, but the humeral surface is much more extensive than that of the scapula.

The =joint capsule= is ample enough to allow the bones to be drawn apart about an inch (ca. 2 to 3 cm.); but this requires a very considerable amount of force unless air is admitted into the joint cavity. The fibrous layer (or capsular ligament) is not attached to the margin of the joint surfaces, but at a distance of one to two centimeters from it. It is strengthened in front by two diverging

elastic bands, which arise on the scapular tuberosity and end on the lips of the bicipital groove. A pad of fat is interposed between the capsule and the tendon of the biceps.

Ligaments are absent from this joint, but the muscles and tendons around it afford remarkable security, so that dislocation seldom or never occurs. The large extent of the head of the humerus is also of importance in this regard.

The principal muscles which are attached around the joint and act as ligaments are: externally, the supraspinatus, infraspinatus, and teres minor; internally, the subscapularis; in front, the biceps and supraspinatus; behind, the triceps.

=Movements.=—While it is a typical enarthrosis in structure, and capable of the various movements of the ball-and-socket joint, the chief normal movements are flexion and extension. In the position of rest the angle formed between the scapula and humerus posteriorly is about 110° to 120°; in flexion it is reduced to about 80°, and in extension it is increased to about 145°. Adduction and abduction are very restricted, the former being limited chiefly by the infraspinatus, the latter by the subscapularis and the low insertion of the superficial pectoral muscles. Rotation is somewhat freer, but does not exceed 33°, when all the muscles are removed (Franck).

THE ELBOW JOINT

This, the cubital articulation (Articulatio cubiti), is a ginglymus formed between the distal extremity of the humerus and the proximal ends of the bones of the forearm.

[Illustration:

FIG. 143.—LEFT ELBOW JOINT OF HORSE, POSTERIOR VIEW. THE CAPSULE IS REMOVED. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =articular surfaces= are: (1) A trochlear surface formed by the condyles of the humerus and the groove between them; (2) the corresponding glenoid cavities and ridge on the proximal extremity of the radius, together with the semilunar notch of the ulna.

The articular surface of the condyles does not extend upon the back of the extremity, but the groove which receives the semilunar notch of the ulna extends up into the olecranon fossa. In the fore part of the groove there is a synovial fossa. The surface on the outer condyle is smaller than that of the inner one, and is subdivided into two unequal parts by a shallow furrow. On the lower part of the semilunar notch and the adjacent part of the ridge on the radius are synovial fossæ.

The =joint capsule= is extremely thin behind, where it forms a pouch in the olecranon fossa under the anconeus muscle and a pad of fat. In front it is strengthened by oblique fibers (Ligamentum obliquum or anterior ligament), and laterally it fuses with the lateral ligaments. Small pouches of the =synovial membrane= lubricate the origins of the flexors of the carpus and digit and the small radio-ulnar joints. There are two lateral ligaments.

The =internal lateral ligament= (Ligamentum collaterale radiale) is attached above to an eminence on the internal epicondyle of the humerus, and divides into two parts: the long, superficial part ends on the inner border of the radius, just below the level of the interosseous space; the deep, short part is inserted into the internal tuberosity of the radius. (The superficial part represents the pronator teres muscle, which is only exceptionally present in the horse.)

The =external lateral ligament= (Ligamentum collaterale ulnare) is short and strong. It is attached above to a depression on the external epicondyle of the humerus, and below to the external tuberosity of the radius, just below the margin of the articular surface.

=Movements.=—This joint is a typical ginglymus, the only movements being flexion and extension around an axis which passes through the upper attachments of the lateral ligaments. In the standing position the articular angle (in front) is about 140° to 150°. The range of movement is about 55° to 60°. Complete extension is prevented chiefly by the tension of the lateral ligaments and the biceps muscle. (The axis of movement is slightly oblique, so that in flexion the forearm is carried somewhat outward.)

[Illustration:

[Illustration:

FIG. 145.—LEFT CARPAL JOINTS OF HORSE, ANTERIOR VIEW.

The capsule has been removed. The smaller ligaments are shown. (After Ellenberger-Baum, Anat. f. Künstler.)]

THE RADIO-ULNAR ARTICULATION

In the foal the shaft of the ulna is attached to the radius above and below the interosseous space by the =interosseous ligament=. Below the space the two bones become fused before adult age is reached. Above the space the ligament usually persists, but may undergo more or less ossification in extreme old age. The =transverse= or =arciform ligaments= (Ligamentum transversum ulnare et radiale ulnæ et radii) consist of fibers which pass above the interosseous space from either border of the shaft of the ulna to the posterior surface of the radius. The proximal radio-ulnar articulation, formed by two small convex facets on the ulna and the corresponding facets on the posterior surface of the proximal extremity of the radius, is inclosed in the capsule of the elbow joint and does not require separate consideration. The distal extremity of the ulna fuses early with the radius, and is, therefore, regarded usually as a part of the latter.

=Movement.=—This is inappreciable, the forearm being fixed in the position of pronation.

THE CARPAL JOINTS

These joints taken together constitute the composite =articulatio carpi=, or what is popularly termed the “knee-joint” in animals.[33] This consists of three chief joints, viz., (1) The =radio-carpal joint=, formed by the distal end of the radius and the proximal row of the carpus; (2) the =intercarpal joint=, formed between the two rows of the carpus; (3) the =carpo-metacarpal joint=, formed between the distal row of the carpus and the proximal ends of the metacarpal bones. The proximal and middle joints may be regarded as ginglymi, although they are not typical or pure examples of hinge-joints. The distal joint is arthrodial. In addition there are arthrodial joints formed between adjacent bones of the same row (Articulationes interosseæ). All these constitute a very composite joint, with numerous ligaments. The articular surfaces have been described in the Osteology.

The =joint capsule= may be regarded, so far as the fibrous part is concerned, as being common to all three joints. It is attached close to the margin of the articular surface of the radius above and the metacarpus below; its deep face is also attached to a considerable extent to the carpal bones and to the small ligaments. Its anterior part, the =dorsal= or =anterior common ligament=, is rather loose, and assists in forming the fibrous canals for the extensor tendons. Its posterior part, the =volar= or =posterior common ligament=, is very thick and dense, and is closely attached to the carpal bones. It levels up the irregularities of the skeleton here, and forms the smooth anterior wall of the carpal canal. It is continued downward to form the =subcarpal= or =inferior check ligament=, which blends with the tendon of the flexor perforans about the middle of the metacarpus.

[Illustration:

FIG. 146.—FRONTAL SECTION OF CARPAL JOINTS OF HORSE (RIGHT SIDE).

_l.u._, External, _l.r._, internal, lateral ligament; _Cr_, radial carpal; _Ci_, intermediate carpal; _Cu_, ulnar carpal; _C2_, second carpal; _C3_, third carpal; _C4_, fourth carpal; _Mc2_, second (internal) metacarpal; _Mc3_, third (large) metacarpal; _Mc4_, fourth (external) metacarpal.]

The =synovial membrane= forms three sacs corresponding to the three joints. The =radio-carpal sac= is the most voluminous; it includes the joints formed by the accessory carpal bone, and also those between the proximal carpal bones as far as the interosseous ligaments. The =intercarpal sac= sends extensions upward and downward between the bones of the two rows as far as the interosseous ligaments; it communicates between the third and fourth carpal bones with the =carpo-metacarpal sac=. The latter is very limited in extent, and is closely applied to the bones; it incloses the carpo-metacarpal joint, and lubricates also the lower parts of the joints between the distal carpal bones and the intermetacarpal joints.

The =external lateral ligament= (Ligamentum carpi collaterale ulnare) is attached above to the external tuberosity of the distal end of the radius. Its long superficial part is attached below to the proximal end of the external small metacarpal chiefly, but some fibers end on the large metacarpal bone. A canal for the lateral extensor tendon separates a short deep band which ends on the ulnar carpal bone. Other deep fibers connect the latter with the fourth carpal bone, and the fourth carpal with the metacarpus.

The =internal lateral ligament= (Ligamentum carpi collaterale radiale) resembles the preceding in general, but is stronger and wider distally. It is attached above to the internal tuberosity of the distal end of the radius and ends below on the proximal ends of the large and inner small metacarpal bones. Deep fasciculi are detached to the radial and second carpal bones. The first carpal bone, when present, is usually embedded in the posterior part of the distal end of the ligament. The posterior part of the ligament is fused with the posterior annular ligament (Ligamentum carpi transversum), and concurs in the formation of a canal for the tendon of the flexor carpi internus.

A number of special short ligaments connect two or more adjacent bones; only the most distinct of these will be described here.

The accessory carpal bone is connected with adjacent bones by three ligaments (Fig. 444). The proximal one is a short band which extends from the accessory carpal in front of the groove on its outer face and is inserted into the distal end of the radius behind the groove for the lateral extensor tendon. A middle band connects the accessory with the ulnar carpal. The distal ligament consists of two strong bands which pass from the lower margin of the accessory to the fourth carpal and the proximal end of the outer metacarpal bone; these bands transmit the action of the muscles, which are inserted into the accessory carpal bone. The other bones of the proximal row are connected by two anterior or dorsal ligaments, which are transverse in direction, and two interosseous ligaments. An oblique ligament passes from an eminence on the posterior surface of the radial carpal bone to a small depression on the radius internal to the facet for the accessory carpal bone.

Two ligaments connect the proximal and distal rows posteriorly. The inner one joins the radial to the second and third carpal, and the outer one attaches the ulnar to the third and fourth carpals.

The bones of the distal row are connected by two strong transverse anterior or dorsal ligaments and two interosseous ligaments.

There are four carpo-metacarpal ligaments. Two oblique anterior bands connect the third carpal with the large metacarpal. Two interosseous ligaments pass downward from the interosseous ligaments of the distal row to end in depressions in the interstices between the proximal ends of the metacarpal bones.

[Illustration:

FIG. 147.—LEFT CARPAL JOINTS OF HORSE, INNER VIEW.

_g_, Radius; _12_, large (third) metacarpal bone. (After Ellenberger-Baum, Anat. für Künstler.)]

=Movements.=—Taking the joint as a whole, the chief movements are flexion and extension. In the standing position the joint is extended. When the joint is flexed, slight lateral movement and rotation can be produced by manipulation. The anterior part of the capsule is, of course, tense during flexion, the posterior part in extension.

The movement practically all occurs at the radio-carpal and intercarpal joints, the articular surfaces of which are widely separated in front during flexion, but remain in contact behind. The distal row remains in contact with the metacarpus. The intermediate and ulnar carpals move together as one piece, but the radial does not move so far as the intermediate, so that the anterior and interosseous ligaments connecting these bones become tense and oblique in direction.

THE FETLOCK JOINT

This, the =metacarpo-phalangeal articulation= (Articulatio metacarpo-phalangea), is a ginglymus formed by the junction of the distal end of the large (third) metacarpal bone, the proximal end of the first phalanx, and the proximal sesamoid bones.

=Articular Surfaces.=—The surface on the large metacarpal bone is approximately cylindrical in curvature, but is divided into two slightly unequal parts by a sagittal ridge. This is received into a sort of socket formed by the first phalanx below and the two sesamoids together with the intersesamoid ligament behind. The latter is a mass of fibro-cartilage in which the sesamoid bones are largely embedded. It extends above the level of the sesamoids, and is grooved to receive the ridge on the metacarpal bone; its posterior surface forms a smooth groove for the deep flexor tendon.

[Illustration:

(After Ellenberger-Baum, Anat. für Künstler.)]

[Illustration:

FIG. 149.—ARTICULAR SURFACES OF FIRST PHALANX AND SESAMOIDS AT FETLOCK, WITH INTERSESAMOID AND SUSPENSORY LIGAMENTS. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =joint capsule= is attached around the margin of the articular surfaces. It is thick and ample in front; here a bursa is interposed between it and the extensor tendons, but the tendons are also attached to the capsule. Posteriorly it forms a thin-walled pouch which extends upward between the metacarpal bone and the suspensory ligament about as high as the point of bifurcation of the latter. The capsule is reinforced by two lateral ligaments.

The =lateral ligaments=, =external= and =internal= (Ligamentum collaterale ulnare, radiale) are partially divided into two layers: the =superficial layer= arises from the eminence on the side of the distal end of the large metacarpal bone, and passes straight to the rough lateral area below the margin of the articular surface of the first phalanx; the =deep layer=, shorter and much stronger, arises in the lateral depression on the distal end of the metacarpal bone, and passes obliquely downward and backward to be inserted into the outer surface of the sesamoid and the proximal end of the first phalanx.

The capsule is further strengthened by a layer of oblique fibers which pass over the lateral ligament on either side and end on the extensor tendon and the proximal extremity of the first phalanx. It may properly be regarded as fascia rather than ligament.

[Illustration:

FIG. 150.—LIGAMENTS AND TENDONS OF DISTAL PART OF LIMB OF HORSE.

=Movements.=—These are of the nature of flexion and extension, the axis of motion passing through the upper attachments of the lateral ligaments. In the ordinary standing position the joint is in a state of partial =dorsal flexion=, the articular angle (in front) being about 140° to 150°. (In the hind limb it is about 5° greater.) Diminution of this angle (sometimes termed “overextension”) is normally very limited on account of the resistance offered by the sesamoidean apparatus, but it varies considerably in amount in different subjects. =Volar flexion= is limited only by contact of the heels with the metacarpus. During volar flexion a small amount of lateral flexion is possible.

THE SESAMOIDEAN LIGAMENTS

Under this head will be described a number of important ligaments which are connected with the sesamoid bones and form a sort of stay apparatus or brace.

The =intersesamoidean ligament= (Ligamentum intersesamoideum) not only fills the space between and unites the sesamoid bones, but also extends above them, entering into the formation of the articular surface of the fetlock joint. Other facts in regard to it have been given above.

The =lateral sesamoidean ligaments=, outer and inner (Ligamenta sesamoidea ulnare et radiale), arise on the abaxial surface of each sesamoid bone, pass forward, and divide into two branches, one of which ends in the depression on the distal end of the large metacarpal bone, the other on the eminence on the proximal end of the first phalanx. They are partly covered by the branches of the suspensory or superior sesamoidean ligament.

[Illustration:

FIG. 151.—DEEP DISSECTION OF DISTAL PART OF RIGHT FORE LIMB OF HORSE, SHOWING JOINTS AND LIGAMENTS, POSTERIOR VIEW.

1, Lateral cartilage; 2, tendon surface of navicular bone; 3, inferior navicular or interosseous ligament; 4, insertion of deep flexor tendon. Small arrows point to openings made in capsules of pastern and coffin joints. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =suspensory= or =superior sesamoidean ligament= (Musculus interosseus medius) lies for the greater part in the metacarpal groove, where it has the form of a wide, thick band. It is attached above to the upper part of the posterior surface of the large metacarpal bone and to the distal row of carpal bones. At the lower fourth of the metacarpus it divides into two diverging branches. Each branch passes to the abaxial face of the corresponding sesamoid, on which a considerable part, is attached. The remainder passes obliquely downward and forward to the anterior surface of the first phalanx, where it joins the extensor tendon. This ligament possesses considerable elasticity, and is the highly modified interosseous medius muscle. It consists mainly of tendinous tissue, but contains a variable amount of striped muscular tissue, especially in its deep part and in young subjects. Its principal function is to support the fetlock, _i. e._, to prevent excessive dorsal flexion of the joint when the weight is put on the limb. The branches which join the common extensor tendon limit volar flexion of the interphalangeal joints in certain phases of movement.

The =inferior sesamoidean ligaments= are three in number—superficial, middle, and deep. The =superficial= or =straight ligament= (Ligamentum sesamoideum rectum) is a flat band and is somewhat wider above than below.[34] It is attached above to the bases of the sesamoid bones and the intersesamoid ligament, below to the complementary fibro-cartilage of the proximal end of the second phalanx. The =middle ligament= is triangular, with thick, rounded margins (Ligamenta obliqua) and a thin central portion.[35] Its base is attached to the sesamoid bones and intersesamoid ligament, and its deep face to the triangular rough area on the posterior surface of the first phalanx. The =deep= or =cruciate ligament= (Ligamenta sesamoidea cruciata) consists of two thin layers of fibers which arise on the base of the sesamoid bones, cross each other, and end on the opposite eminence on the proximal end of the first phalanx.

The =short sesamoidean ligaments= (Ligamenta sesamoidea brevia) are best seen by opening the joint in front and pushing the sesamoid bones backward; they are covered by the synovial membrane. Each is a short band which extends from the anterior part of the base of the sesamoid bone outward to the posterior margin of the articular surface of the first phalanx.

The inferior sesamoidean ligaments may be regarded as digital continuations of the suspensory ligament, the sesamoid bones being intercalated in this remarkable stay apparatus by which the fetlock is supported and concussion diminished.

THE PASTERN JOINT

This, the =proximal interphalangeal articulation= (Articulatio phalangis secundæ), is a ginglymus formed by the junction of the distal end of the first phalanx and the proximal end of the second phalanx.

The =articular surfaces= are: (1) On the first phalanx, two slightly unequal convex areas with an intermediate shallow groove; (2) on the second phalanx, a corresponding surface, completed behind by a plate of fibro-cartilage.

The =joint capsule= is close fitting in front and laterally, where it blends with the extensor tendon and the lateral ligaments respectively. Behind it pouches upward a little and is reinforced by the straight sesamoidean ligament and the branches of the superficial flexor tendon.

There are two lateral and four volar ligaments.

The =lateral ligaments=, internal and external (Ligamentum collaterale radiale, ulnare) are very short and strong bands which are attached above on the eminence and depression on each side of the distal end of the first phalanx, and below on the eminence on either side of the proximal end of the second phalanx. The direction of the ligaments is about vertical and, therefore, does not correspond to the digital axis.

The =volar= or =posterior ligaments= consist of central and lateral pairs of bands which are attached below to the posterior margin of the proximal end of the second phalanx and its complementary fibro-cartilage. The lateral pair is attached above to the middle of the borders of the first phalanx, the central pair lower down and on the margin of the triangular rough area.

These ligaments are very commonly thickened as a result of chronic inflammation, and then are not well defined. The central ones blend below with the branches of the superficial flexor tendon and with the straight sesamoidean ligament.

=Movements.=—These are very limited, and consist of flexion and extension. The axis of motion passes transversely through the distal end of the first phalanx. In the standing position the joint is extended. A small amount of volar flexion is possible, and in this

position slight lateral flexion and rotation can be produced by manipulation. Dorsal flexion is prevented by the lateral, volar, and straight sesamoidean ligaments.

THE COFFIN JOINT

This joint, technically termed the =distal interphalangeal articulation= (Articulatio phalangis tertiæ), is a ginglymus formed by the junction of the second and third phalanges and the third sesamoid bone.

=Articular Surfaces.=—The surface on the distal end of the second phalanx is convex from before backward, concave transversely. The articular surface of the third phalanx slopes sharply upward and forward; its central part is prominent, and is flanked by two glenoid cavities. It is completed behind by the articular surface of the third sesamoid or navicular bone.

[Illustration:

FIG. 152.—LATERAL LIGAMENTS OF PASTERN JOINT AND SUSPENSORY LIGAMENTS OF NAVICULAR BONE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

=Joint Capsule.=—This is attached around the margins of the articular surfaces. In front and laterally it is tight, and is blended with the extensor tendon and the lateral ligaments respectively. Posteriorly, it forms a considerable pouch which extends upward to about the middle of the second phalanx, where it is separated by a fibrous membrane from the digital synovial sheath. Laterally small pouches project outward (especially during volar flexion) against the lateral cartilages, just behind the lateral ligaments.[36]

=Ligaments.=—The =lateral ligaments=, external and internal (Ligamentum collaterale ulnare, radiale), are short strong bands which are attached above in the depressions on either side of the lower part of the second phalanx, under cover of the lateral cartilage. They widen below and end in the depressions on either side of the extensor process and on the anterior end of the lateral cartilages.

The =suspensory navicular ligaments=, external and internal (Ligamentum sesamoideum collaterale ulnare, radiale),[37] are strong, somewhat elastic bands, which form a sort of suspensory apparatus for the third sesamoid. They are attached superiorly in and above the depressions on either side of the distal end of the first phalanx and are here partly blended with the lateral ligaments of the pastern joint. They are directed obliquely downward and backward, and end chiefly on the ends and proximal border of the third sesamoid, but detach a branch to the inner surface of each lateral cartilage and wing of the third phalanx.

The =inferior navicular ligament= (Ligamentum phalangeo-sesamoideum) reinforces the capsule interiorly. It is a strong layer of fibers which extend from the distal border of the third sesamoid to the tendon surface of the third phalanx, near the posterior margin of the articular surface.

=Movements.=—The chief movements are flexion and extension. In the standing position the joint is extended. During volar flexion a very small amount of lateral movement and rotation can be produced by manipulation. Dorsal flexion is very limited.

Dorsal flexion appears to be checked mainly by the deep flexor tendon, since in cases of rupture of the latter the toe turns up. The slight mobility of the posterior part of the socket for the second phalanx (formed by the third sesamoid) diminishes concussion when the weight comes on the foot.

LIGAMENTS OF THE LATERAL CARTILAGES

In addition to the bands mentioned above, which attach the lateral cartilages to the extremities of the navicular bone, there are three ligaments on either side which attach the cartilages to the phalanges.

An ill-defined elastic band passes from the middle part of the border of the first phalanx to the upper part of the cartilage, detaching a branch to the plantar cushion.

A short strong band connects the anterior extremity of the cartilage with the rough eminence on the second phalanx in front of the attachment of the lateral ligament of the coffin joint.

The lower border of the cartilage is covered externally by fibers which attach it to the wing of the third phalanx.

THE ARTICULATIONS OF THE PELVIC LIMB

THE SACRO-ILIAC ARTICULATION

This joint (Articulatio sacro-iliaca) is a diarthrosis formed between the auricular surfaces of the sacrum and ilium. These surfaces are not smooth in the adult, but are marked by eminences and depressions, and are covered by a thin layer of cartilage. The joint cavity is a mere cleft, and is often crossed by fibrous bands.

The =capsule= is very close fitting, and is attached around the margins of the articular surfaces. It is reinforced by the =ventral sacro-iliac ligament= (Ligamentum sacro-iliacum ventrale), which surrounds the joint, and is exceedingly strong above.

The =movements= are inappreciable in the adult—stability, not mobility, being the chief desideratum.

The following ligaments may be regarded as accessory to the joint, although not directly connected with it.

The =dorsal sacro-iliac ligament= (Ligamentum sacro-iliacum dorsale breve) is a strong band which is attached to the internal angle (Tuber sacrale) of the ilium and the summits of the sacral spines.

The =lateral sacro-iliac ligament= (Ligamentum sacro-iliacum dorsale longum) is a triangular, thick sheet which is attached in front to the internal angle and border of the ilium above the great sciatic notch, and below to the lateral border of the sacrum. It blends above with the dorsal sacro-iliac ligament, below with the sacro-sciatic ligament, and behind with the coccygeal fascia.

The =sacro-sciatic ligament= (Ligamentum sacrospinosum et tuberosum) is a quadrilateral sheet which completes the lateral pelvic wall. Its upper border is attached to the border of the sacrum and the transverse processes of the first and second coccygeal vertebræ. Its lower border is attached to the superior ischiatic spine and tuber ischii. Between these it bridges over the external border of the ischium and completes the lesser sciatic foramen. The anterior border is concave, and completes the greater sciatic foramen. The posterior border is fused with the vertebral head of the semimembranosus muscle.

The =ilio-lumbar ligament= (Ligamentum ilio-lumbale) is a triangular sheet which attaches the ends of the lumbar transverse processes to the ventral surface of the ilium below the attachment of the longissimus muscle (Fig. 184).

[Illustration:

FIG. 153.—LEFT OS COXÆ AND ADJACENT PARTS OF SACRUM AND FEMUR OF HORSE. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

SYMPHYSIS PELVIS

The =symphysis pelvis= is formed by the junction of the two ossa coxarum at the ventral median line. In the young subject the bones are united by a layer of cartilage; in the adult the latter is gradually replaced by bone, the process beginning in the pubic portion and extending backward. The union is strengthened by white fibrous tissue above and below, and a transverse band also covers the anterior border of the pubis (pecten). No appreciable movement occurs even before synostosis takes place.

OBTURATOR MEMBRANE

This (Membrana obturatoria) is a thin layer of fibrous tissue which covers the obturator foramen, leaving, however, a passage (Canalis obturatorius) for the obturator vessels and nerve.

THE HIP JOINT

This joint (Articulatio coxæ) is an enarthrosis formed by the proximal end of the femur and the acetabulum.

=Articular Surfaces.=—The head of the femur presents an almost hemispherical articular surface, which is continued a short distance on the upper surface of the neck. It is more extensive than the socket which receives it. Internally it is cut into by a deep notch for the attachment of the round and pubo-femoral ligaments. The acetabulum is a typical cotyloid cavity. Its articular surface is somewhat crescentic, being deeply cut into internally by the acetabular notch and fossa. It is increased and deepened by a ring of fibro-cartilage, the =cotyloid ligament= (Labrum glenoidale), which is attached to the bony margin; that part of the ligament which crosses the notch is called the =transverse ligament= (Fig. 456).

[Illustration:

FIG. 154.—PELVIC LIGAMENTS AND HIP JOINT.

_1_, Dorsal sacro-iliac ligament; _2_, lateral sacro-iliac ligament; _3_, sacro-sciatic ligament; _4_, greater sciatic foramen; _5_, lesser sciatic foramen; _6_, line of attachment of intermuscular septum between biceps femoris and semitendinosus; _7_, capsule of hip joint; _8_, rectus parvus or capsularis muscle; _9_, outer tendon of origin of biceps femoris; _10_, internal, _11_, external, angle of ilium; _12_, shaft of ilium; _13_, superior ischiatic spine; _14_, pubis; _15_, tuber ischii; _16_, trochanter major; _17_, semimembranosus; _18_, fifth lumbar spine; _19_, _20_, first and second coccygeal vertebræ.]

The =joint capsule= is roomy. It is attached around the margin of the acetabulum and the neck of the femur. It is thickest externally.

The attachment on the femur is about 1 cm. from the margin of the articular surface, except above, where 2 to 3 cm. of the neck is intracapsular. A thin oblique band corresponding in direction with the rectus parvus muscle reinforces the antero-external part of the capsule; this appears to be the feeble homologue of the very strong ilio-femoral ligament of man. The capsule is very thin under the ilio-psoas, and is adherent to the muscle. Internally, its fibrous part is perforated by the pubo-femoral and round ligaments and the articular vessels.

The =round ligament= (Ligamentum teres) is a strong hand which is attached in the subpubic groove close to the acetabular notch, passes outward, and ends in the notch on the head of the femur (Fig. 456).

The =pubo-femoral ligament= (Ligamentum accessorium) does not occur in the domestic animals other than the equidæ. It is a strong band detached from the prepubic tendon of the abdominal muscles (Fig. 456). It is directed outward, backward, and upward, passes through the acetabular notch above the transverse ligament, and ends behind the round ligament in the notch on the head of the femur. The origin of the pectineus muscle is perforated by the ligament, which furnishes attachment to the greater part of the fibers of the muscle.

[Illustration:

FIG. 155.—LEFT STIFLE JOINT OF HORSE, EXTERNAL VIEW, IN PARTIAL FLEXION.

The capsules have been removed. _18_, Femur; _20_, patella; _21_, tibia; _a″_, internal patellar ligament; _b_, external femoro-patellar ligament; _d_, external semilunar cartilage. (After Ellenberger-Baum, Anat. für Künstler.)]

The =synovial membrane= is reflected over the intracapsular parts of these ligaments and covers the fossa acetabuli. A pouch also extends from the acetabular notch for a variable distance along the subpubic groove above the pubo-femoral ligament.

=Movements.=—This joint is capable of all the movements of a ball-and-socket joint, viz., flexion, extension, abduction, adduction, rotation, and circumduction. The greatest range of movement is displayed in flexion and extension. When standing at rest, the joint is partially flexed, the articular angle (in front) being about 100° to 115°. The other movements occur to a very limited extent in normal action.

Abduction appears to be checked by tension of the round ligament. The pubo-femoral ligament is tensed most promptly by inward rotation of the thigh.

THE STIFLE JOINT

This joint (Articulatio genu), which corresponds to the knee-joint of man, is the largest and most elaborate of all the articulations. Taken as a whole, it may be classed as a ginglymus, although it is not a typical example of the group. In reality it consists of two joints—the =femoro-patellar= and the =femoro-tibial=.

The =femoro-patellar articulation= (Articulatio femoro-patellaris) is formed between the trochlea of the femur and the articular surface of the patella.

[Illustration:

FIG. 156.—LEFT STIFLE JOINT OF HORSE, LATERAL VIEW.

The capsules are distended and the external patellar ligament is removed.]

=Articular Surfaces.=—The trochlea consists of two slightly oblique ridges, with a wide and deep groove between them. The inner ridge is much the larger of the two, especially at its upper part, which is wide and rounded. The outer ridge is much narrower, and is more regularly curved; its upper part lies about an inch behind a frontal plane tangent to the inner ridge. The articular surface of the patella is much smaller than that of the trochlea. It is completed internally by a supplementary plate of fibro-cartilage (Fibrocartilago patellæ), which curves over the internal surface of the inner lip of the trochlea. A narrow strip of cartilage is found along the outer border also. The articular cartilage on the trochlea completely covers both surfaces of the inner ridge, but only a narrow marginal area on the external surface of the outer ridge.

=Joint Capsule.=—This is thin and is very capacious. On the patella it is attached around the margin of the articular surface, but on the femur the line of attachment is at a varying distance from the articular surface. On the inner side it is an inch or more from the articular cartilage; on the outer side and above, about half an inch. It pouches upward under the quadriceps femoris for a distance of two or three inches, a pad of fat separating the capsule from the muscle. Below the patella it is separated from the straight ligaments by a thick pad of fat, but inferiorly it is in contact with the femoro-patellar capsules. The joint cavity is the most extensive in the body. It usually communicates with the inner femoro-tibial joint cavity by a slit-like opening situated at the lowest part of the inner ridge of the trochlea. A similar, but smaller, communication with the outer femoro-patellar capsule is often found at the lowest part of the outer ridge.

The inner communication appears to be constant in adult horses, but is liable to be overlooked on account of the fact that it is covered by a valvular fold of the synovial membrane. It is about half an inch wide, and lies under the narrow articular area which connects the trochlea and internal condyle. The outer communication occurs in 18 to 25 per cent. of cases, according to Baum. It is instructive to distend this capsule and thus obtain an idea of its potential capacity and relations ([Fig. 156]).

[Illustration:

FIG. 157.—STIFLE JOINT OF HORSE, FRONT VIEW, IN EXTENSION.

The capsules are removed. _18_, Femur; _20_, patella; _21_, tibia. (After Ellenberger-Baum, Anat. für Künstler.)]

=Ligaments.=—The =lateral femoro-patellar ligaments=, external and internal (Ligamentum femoro-patellare fibulare, tibiale), are two thin bands which reinforce the capsule on either side. The external ligament is fairly distinct; it arises from the external epicondyle of the femur just above the lateral femoro-tibial ligament, and ends on the external border of the patella. The internal ligament is thinner and is not distinct from the capsule; it arises above the internal epicondyle, and ends on the patellar fibro-cartilage.

The =patellar ligaments= (Ligamenta patellæ), also called the straight ligaments of the patella, are three very strong bands which attach the patella to the tuberosity of the tibia. The =external patellar ligament= is attached above to the outer part of the anterior surface of the patella, and below to the outer part of the tuberosity. It receives a strong tendon from the biceps femoris muscle. The =middle patellar ligament= extends from the front of the apex of the patella to the lower part of the groove on the tuberosity of the tibia, a bursa being interposed between the ligament and the upper part of the groove. The =internal patellar ligament= is attached above to the patellar fibro-cartilage, and ends on the tuberosity of the tibia, internally to the groove. It is joined by the common aponeurosis of the gracilis and sartorius. These so-called ligaments are, in reality, the tendons of insertion of the quadriceps femoris muscle, and transmit the action of the latter to the tibia; they also function similarly for the other muscles attached to them as noted above.

It will be noticed that the upper attachments are further apart than the lower ones, so that the ligaments converge below. The inner ligament is especially oblique. The middle ligament is more deeply placed than the others, and therefore cannot usually be felt distinctly in the living animal.

[Illustration:

FIG. 158.—SEMILUNAR CARTILAGES AND CRUCIAL LIGAMENTS OF RIGHT STIFLE OF HORSE.

_F_, Femoral ligament of external cartilage. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =femoro-tibial articulation= (Articulatio femoro-tibialis) is formed between the condyles of the femur, the proximal end of the tibia, and the interposed semilunar cartilages.

=Articular Surfaces.=—The condyles of the femur are slightly oblique in direction. The articular surface of the outer one is more strongly curved than that of the inner one; the latter is confluent below with the inner ridge of the trochlea, while the narrow ridge which connects the external condyle with the trochlea is usually non-articular. The saddle-shaped surfaces of the condyles of the tibia are not adapted to the femoral condyles, and are in contact with only a small part of them.

[Illustration:

FIG. 159.—PROXIMAL ENDS OF RIGHT TIBIA AND FIBULA OF HORSE, WITH SEMILUNAR CARTILAGES AND CRUCIAL LIGAMENTS, EXTERNAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The =semilunar cartilages= (Meniscus lateralis, medialis) are two C-shaped or crescentic discs of fibro-cartilage which produce congruence in the articular surfaces. Each has an upper concave surface adapted to the condyle of the femur, and a lower surface which fits the corresponding condyle of the tibia. The external cartilage does not cover the outer and posterior part of the condyle, over which the tendon of origin of the popliteus muscle plays. The peripheral border is thick and convex, the central one very thin and concave. The fibrous ends or =cornua= are attached to the tibia in front of and behind the spine. The external cartilage has a third attachment by means of an oblique band (Ligamentum femorale menisci lateralis) which passes from the posterior cornu to the posterior part of the intercondyloid fossa of the femur.

The cornua of the internal cartilage (Ligamenta tibiæ anterius et posterius menisci medialis) are attached in front of and behind the inner eminence of the spine. The anterior cornu of the external cartilage (Ligamentum tibiæ anterius menisci lateralis) is attached in front of the outer eminence of the spine. The posterior cornu bifurcates; the lower branch (Ligamentum tibiæ posterius menisci lateralis) is inserted at the popliteal notch, the upper (Ligamentum femorale menisci lateralis) in a small fossa in the extreme posterior part of the intercondyloid fossa.

The =joint capsule= is attached to the margin of the tibial articular surface, but on the femur the line of attachment is for the greater part about half an inch from the articular margin. It is also attached to the convex borders of the semilunar cartilages and to the crucial ligaments. It is strong posteriorly, but in front it practically consists only of the synovial layer. There are two synovial sacs, corresponding to the double nature of the articular surfaces; they do not usually communicate, and each is partially divided into an upper and a lower compartment by the semilunar cartilage. The inner sac pouches upward about half an inch over the condyle of the femur. The external sac invests the tendon of origin of the popliteus muscle, and also pouches downward about three or four inches (ca. 8 to 10 cm.) beneath the peroneus tertius and long extensor muscles (Fig. 156). As stated above, the outer sac sometimes communicates with the femoro-patellar joint cavity, and the inner sac usually, if not always, does so in the adult.

[Illustration:

FIG. 160.—LEFT STIFLE JOINT OF HORSE, INTERNAL VIEW IN EXTREME EXTENSION.[38]

_18_, Femur; _20_, patella (base); _21_, tibia; _d_, internal semilunar cartilage. (After Ellenberger-Baum, Anat. für Künstler.)]

=Ligaments.=—There are four of these—two lateral and two crucial.

The =internal lateral ligament= (Ligamentum collaterale tibiale) is attached above to the prominent internal epicondyle of the femur, and below to a rough area below the margin of the internal condyle of the tibia.

The =external lateral ligament= (Ligamentum collaterale fibulare) is somewhat thicker; it arises from the upper depression on the external epicondyle, and ends on the head of the fibula. It covers the tendon of the origin of the popliteus muscle, and a bursa is interposed between the lower part of the ligament and the margin of the external condyle of the tibia.

The =crucial ligaments= are two strong rounded bands situated mainly in the intercondyloid fossa of the femur, between the two synovial sacs. They cross each other somewhat in the form of an X, and are named according to their tibial attachments. The =anterior crucial ligament= (Ligamentum cruciatum anterius) arises in the central fossa on the tibial spine, extends upward and backward, and ends on the upper part of the inner surface of the external condyle of the femur. The =posterior crucial ligament= (Ligamentum cruciatum posterius) is internal to the preceding, and is somewhat larger. It is attached to an eminence at the popliteal notch of the tibia, is directed upward and forward, and ends in the anterior part of the intercondyloid fossa of the femur.

[Illustration:

FIG. 161.—RIGHT STIFLE JOINT OF HORSE; SAGITTAL SECTION PASSING THROUGH OUTER PART OF INNER RIDGE OF TROCHLEA AND INTERCONDYLOID FOSSA.

_1_, Anterior crucial ligament; _2_, posterior crucial ligament; _3_, posterior cornu of internal semilunar cartilage; _4_, femoral ligament of external semilunar cartilage; _5_, articular artery; _6_, part of vastus internus.]

It may be added that these ligaments do not lie in a sagittal plane, but are somewhat twisted across each other; outward rotation of the leg untwists and slackens them.

=Movements.=—The principal movements of the stifle joint as a whole are flexion and extension. In the ordinary standing position the articular angle (behind) is about 140° to 150°. Flexion is limited only by contact of the leg with the thigh if the hock is also flexed. Extension is incomplete, _i. e._, the femur and tibia cannot be brought into the same straight line. Rotation is limited, and is freest during semiflexion. The patella glides on the femoral trochlea upward in extension, downward in flexion.

Extension is checked mainly by tension of the crucial and lateral ligaments. In extreme extension, which is accompanied by slight outward rotation of the leg, the patella can be pushed upward and inward so that its fibro-cartilage hooks over the upper end of the inner ridge of the trochlea, but it will not remain there unless held in position. When pressure is removed, the base of the patella tips forward and the cartilage lies upon the most prominent part of the trochlear ridge. During flexion, which is accompanied by slight inward rotation of the leg, the condyles of the femur and the semilunar cartilages glide backward on the tibia; the movement of the external condyle and cartilage is greater than that of the inner one. In extreme flexion the patellar and posterior crucial ligaments are tense; the other ligaments are relaxed. The movement of the patella is gliding with coaptation, _i. e._, different parts of the opposing articular surfaces come into contact successively. Only a narrow transverse strip (ca. 1.5 to 2 cm. wide) of the patella is in contact with the trochlea at a time.

TIBIO-FIBULAR ARTICULATION

The head of the fibula articulates with a crescentic facet just below the outer margin of the external condyle of the tibia. The =joint capsule= is strong and close. The shaft of the fibula is attached to the external border of the tibia by the =interosseous membrane= of the leg (Membrana interossea cruris); this is perforated about an inch from its proximal end by an opening which transmits the anterior tibial vessels to the front of the tibia. A fibrous cord usually extends from the distal end of the shaft of the fibula to the external malleolus. The latter is the distal end of the fibula which has fused with the tibia. No appreciable movement occurs in this joint.

THE HOCK JOINT

This is a composite joint made up of a number of articulations (Articulationes tarsi). These are: (1) The tibio-tarsal articulation; (2) the intertarsal articulations; (3) the tarso-metatarsal articulation.

The =tibio-tarsal articulation= (Articulatio talo-cruralis) is a typical ginglymus formed by the trochlea of the tibial tarsal bone (astragalus or talus) and the corresponding surface of the distal end of the tibia. The ridges and grooves of these surfaces are directed obliquely forward and outward at an angle of about 12° to 15°, with a sagittal plane. The trochlear surface is about twice as extensive as that on the tibia, and its ridges have a spiral curvature. The other articulations are arthrodia, which have joint surfaces and ligaments of such a nature as to allow only a minimal amount of gliding motion.

As in the case of the carpal joints, it is convenient to describe first the common capsule and ligaments, which are the more important practically, and then to consider very briefly the special ligaments.

The fibrous part of the =joint capsule= is attached around the margin of the tibial articular surface above and the metatarsal surfaces below; it is also attached in part to the free surface of the bones which it covers, and blends with the lateral ligaments. Its anterior part (anterior ligament) is rather thin; in distention of the capsule, as in “bog-spavin,” its antero-internal part, which is not bound down by the tendons passing over the joint, forms a fluctuating swelling over the inner ridge of the trochlea. The posterior part (posterior and tarso-metatarsal ligaments) is very thick, and is intimately attached to the tarsal bones. Its superficial face is in part cartilaginous, and forms a smooth surface for the perforans tendon. Superiorly, it pouches upward behind the distal end of the tibia for a distance of about two inches (ca. 5 cm.). Interiorly, it is continued downward, forming the =subtarsal= or =check ligament=, which unites with the perforans tendon about the middle of the metatarsus.

[Illustration:

FIG. 164.—LEFT HOCK JOINT OF HORSE, ANTERIOR VIEW.

_21_, Tibia; _22_, trochlea of tibial tarsal bone; _25_, large metatarsal bone; _50_, dorsal or oblique ligament. (After Ellenberger-Baum, Anat. für Künstler.)]

There are four =synovial sacs=: 1. The =tibio-tarsal sac= lubricates the proximal joint, and is much the largest and most important. It is chiefly involved in the swelling produced by excess of fluid in the joint cavity, when the capsule bulges antero-internally and postero-superiorly. 2. The =first intertarsal sac= lines the joints formed by the tibial and fibular tarsal bones above, and the central and fourth tarsals below; it communicates in front with the proximal synovial capsule. 3. The =second intertarsal sac= lubricates the joints formed between the central tarsal and the bones below and on either side. 4. The =tarso-metatarsal sac= lubricates the joints formed between the tarsal and metatarsal bones, those between the proximal ends of the metatarsal bones, and those formed by the third tarsal with the bones on either side.

=Common Ligaments.=—The =external lateral ligament= (Ligamentum collaterale fibulare longum et breve) consists of two distinct bands which cross each other. The =long= (superficial) =ligament= arises on the posterior part of the external malleolus, is directed almost straight downward, and is attached to the fibular and fourth tarsal bones and the large and external small metatarsal bones. It forms a canal for the lateral extensor tendon. The =short= (deep) =ligament= arises on the anterior part of the external malleolus, is directed chiefly backward, and ends on the rough excavation on the external surface of the tibial tarsal and the adjacent surface of the fibular tarsal bone.

[Illustration:

FIG. 165.—LEFT HOCK JOINT OF HORSE, POSTERIOR VIEW.

_21_, Tibia; _24_, tuber calcis. (After Ellenberger-Baum, Anat. für Künstler.)]

The =internal lateral ligament= (Ligamentum collaterale tibiale longum et breve) also consists of two parts which cross each other. The =long ligament= arises on the posterior part of the internal malleolus, becomes wider below, and is attached on the lower tuberosity of the tibial tarsal, the large and outer small metatarsal bones, and the inner surface of the lower tarsal bones which it covers. The =short ligament= lies largely under cover of the long one. It extends from the anterior part of the internal malleolus, runs backward and somewhat downward, and divides into two branches; one of these ends on the upper tuberosity on the inner surface of the tibial tarsal bone, the other on the sustentaculum tali.

The =plantar= or =calcaneo-metatarsal ligament= (Ligamentum tarsi plantare) is a very strong flat band which covers the outer part of the posterior surface of the tarsus. It is attached to the posterior surface of the fibular and fourth tarsal bones and the proximal end of the external metatarsal bone.

The =dorsal= or =oblique ligament= (Ligamentum tarsi dorsale) is a triangular sheet which is attached above to the lower tuberosity on the inner face of the tibial tarsal bone, and spreads out below on the central and third tarsal bones, and the proximal ends of the large and inner small metatarsal bones, to all of which it is attached.

=Special Ligaments.=—A considerable number of short bands which connect adjacent bones of the tarsus and metatarsus are described by various authors; some of these are quite distinct; others are difficult to isolate. Most of them are not of sufficient importance to justify detailed description.

(1) The =tibial= and =fibular tarsal= bones are united by four bands (astragalo-calcaneal ligaments). The =internal ligament= extends from the sustentaculum tali to the adjacent part of the tibia tarsal, blending with the short lateral ligament. The =external ligament= extends from the anterior process of the fibular tarsal to the adjacent part of the external ridge of the trochlea. The =superior ligament= extends from the posterior margin of the trochlea to the fibular tarsal. The =interosseous ligament= is deeply placed in the sinus tarsi between the two bones, and is attached in the rough areas of the opposed surfaces.

(2) The smaller bones are attached to each other as follows: The central and third tarsal are united by an interosseous and an oblique anterior ligament (scaphoido-cunean ligaments). The central and fourth tarsal are united by an interosseous and a transverse external ligament (cuboido-scaphoid ligament). The third and fourth tarsals are similarly connected (cuboido-cunean ligaments). The third tarsal is joined by an interosseous (intercunean) ligament to the (fused) first and second tarsals; the latter are connected with the fourth tarsal by a transverse posterior ligament.

(3) The smaller bones are connected with the upper row as follows: The central is attached to the tibial tarsal by posterior and interosseous (astragalo-seaphoid) ligaments, and to the fibular tarsal by a short oblique (calcaneo-scaphoid) band. The fourth is attached to the fibular tarsal by interosseous and posterior (calcaneo-cuboid) ligaments. The (fused) first and second tarsals are connected with the fibular tarsal by a posterior (calcaneo-cunean) ligament.

(4) The lower tarsal bones are connected with the metatarsus by tarso-metatarsal ligaments, which are not distinct from the common ligaments, except in the case of the interosseous ligament between the third tarsal and metatarsal bones.

[Illustration:

FIG. 166.—SAGITTAL SECTION OF HOCK OF HORSE.]

=Movements.=—These are flexion and extension, which take place at the tibio-tarsal joint. The movements between the tarsal bones, and between the latter and the metatarsus, are so limited as to be negligible so far as the action of the joint as a whole is concerned. In the standing position the articular angle (in front) is about 150° to 160°. Complete extension is prevented by tension of the lateral ligaments. Flexion is checked only by contact of the metatarsus with the leg, provided the stifle joint is also flexed. Owing to the fact that the axis of motion is slightly oblique, the lower part of the limb deviates somewhat outward during flexion.

The movements of the hock joint must correspond with those of the stifle on account of the tendinous bands in front and behind (peroneus tertius and flexor perforatus), which extend from the lower part of the femur to the tarsus and metatarsus.

The remaining joints differ in no material respect from those of the thoracic limb.

COMPARATIVE ARTHROLOGY[39]

JOINTS AND LIGAMENTS OF THE VERTEBRÆ

=Ox.=—The ligamentum nuchæ is better developed than in the horse. The funicular part is clearly divided into two lateral halves, which are round at their occipital attachment, but from the axis backward become rapidly wider and flat. This wide portion is almost sagittal, lies on either side of the vertebral spines, and is covered by the trapezius and rhomboideus muscles. From the highest part of the withers (third thoracic spine) it gradually diminishes in size and fades out in the lumbar region. The lamellar part is thick, and consists of anterior and posterior parts. The anterior part is double; its fibers proceed from the funicular part to the second, third, and fourth cervical spines. The posterior part is single; its fibers extend from the first thoracic spine to the fifth, sixth, and seventh cervical spines.

[Illustration:

FIG. 167.—LIGAMENTUM NUCHÆ OF OX.

_a_, Funicular part; _b_, wide portion; _c_, _d_, lamellar part; _e_, interspinous ligaments; _1_, spinous process of first thoracic vertebra; _2_, axis. (Ellenberger-Baum, Anat. d. Haustiere.)]

The inferior common ligament is very strong in the lumbar region.

The intervertebral fibro-cartilages are thicker than in the horse.

The interspinous ligaments of the back and loins consist largely of elastic tissue.

There are no intertransverse joints in the lumbar region.

=Pig.=—The ligamentum nuchæ is represented by a fibrous raphé and thin layers of elastic tissue which extend between the cervical spines.

The atlanto-occipital and atlanto-axial joints resemble those of the dog.

The interspinous ligaments of the neck are elastic.

=Dog.=—The ligamentum nuchæ consists of a small fibrous band which extends from the spine of the axis to the anterior thoracic spines; it may be regarded as a mere fibrous raphé between the right and left muscles.

There are interspinous muscles instead of ligaments in the neck.

There are three ligaments in connection with the odontoid process. The two alar ligaments (Ligamenta alaria) arise on either side of the odontoid process, diverge, and end on either side of the foramen magnum. The transverse ligament of the atlas (Ligamentum transversum atlantis) stretches across the dorsal surface of the odontoid process and binds it down on the ventral arch of the atlas, a bursa being interposed. It is attached on either side to the lateral masses of the atlas.

The two capsules of the atlanto-occipital joint communicate with each other, and usually with the capsule of the atlanto-axial joint also.

ARTICULATIONS OF THE THORAX

=Ox.=—The second to the eleventh costo-chondral joints inclusive are diarthroses with close capsules, reinforced externally. (They are synchondroses in the sheep.) The upper parts of the cartilages are attached to each other by distinct elastic ligaments (Ligamenta intercostalia).

The first pair of chondro-sternal joints are separate from each other; intercrossing fibers unite the costo-chondral junctions above the joints.

The first segment of the sternum forms a diarthrosis with the body. The anterior joint surface is concave, the posterior convex. The joint (Articulatio intersternalis) is surrounded by a close capsule, and the joint surfaces are attached to each by a small intraarticular ligament. Limited lateral movement is possible. (In the sheep the joint is a synchondrosis.)

Both surfaces of the sternum are covered by a layer of fibrous tissue.

=Pig.=—The second to the fifth or sixth costo-chondral joints are diarthroses. The intersternal articulation and the sternal ligaments resemble those of the ox.

=Dog.=—The first chondro-sternal joints do not coalesce.

The internal sternal ligament divides into three bands.

TEMPORO-MANDIBULAR ARTICULATION

=Ox.=—The articular surfaces are of such a character as to permit more extensive lateral movement than in the horse.

The condyle of the mandible is relatively small and is concave transversely. The temporal articular surface is extensive and is convex in both directions. The postglenoid process is small.

=Pig.=—The considerable longitudinal diameter of the temporal articular surfaces and the very small size of the postglenoid process allow great freedom of protraction and retraction of the lower jaw. Lateral movement is limited. The posterior ligament is absent.

=Dog.=—The articular surfaces allow extremely little lateral or gliding movement. They are cylindrical in curvature, and the interarticular disc is very thin. The posterior ligament is absent.

The other articulations of the skull are sufficiently described in the Osteology.

Articulations of the Thoracic Limb

SHOULDER JOINT

=Ox.=—The articular angle is about 100°.

=Pig and Dog.=—The joint capsule communicates freely with the bicipital bursa. There is a rudimentary marginal cartilage around the rim of the glenoid cavity. In the dog there is usually a strong band extending from the acromion to the outer part of the capsule; another band (Ligamentum coraco-acromiale) often stretches between the scapular tuberosity and the acromion.

ELBOW JOINT

=Ox.=—No important differences exist. The upper part of the interosseous radio-ulnar ligament is commonly ossified in the adult.

=Pig.=—There are no important differences. The radius and ulna are so firmly united by the interosseous ligament as to prevent any appreciable movement between them.

=Dog.=—The joint capsule is reinforced in front by an oblique ligament which arises on the front of the external condyle of the humerus above the joint surface, and joins the terminal part of the biceps and brachialis below. The external lateral ligament is thick and divides into two parts; the anterior part is attached to the radius and blends with the annular ligament; the posterior part widens below, forming a sort of cap, and is attached to the ulna. The internal lateral ligament also divides into two branches; the anterior branch ends on the inner surface of the neck of the radius; the posterior enters the interosseous space and is attached to both bones. An elastic band (Ligamentum olecrani) extends from the outer surface of the internal epicondyle to the anterior border of the ulna.

There are two radio-ulnar joints. The proximal radio-ulnar joint is included in the capsule of the elbow, but is provided with an annular ligament which extends from the lower part of the external ligament across the front of the proximal end of the radius to the ulna, blending with the biceps and brachialis tendons. The distal joint is formed by a concave facet on the radius and a convex one on the radius, and is surrounded by a tight capsule. The interosseous membrane unites the shafts of the two bones. The movements consist of limited rotation of the radius (ca. 20°), carrying the paw with it. The ordinary position is termed pronation; outward rotation is supination.[40]

THE CARPAL JOINTS

These have the same general arrangement as in the horse. Numerous minor differences naturally exist, but must be excluded from this brief account, which contains only important special features.

The lateral movements are freer, especially in the dog, but flexion is not so complete: the anatomical explanation of these facts lies in the nature of the articular surfaces and certain ligamentous differences. The lateral ligaments are much weaker, the long external one being especially small in the ox. Two oblique, somewhat elastic, bands cross the front of the radio-carpal and intercarpal joints. The proximal one is attached to the distal end of the radius and passes downward and outward to the ulnar carpal bone; the other one connects the radial and fourth carpal bones in a similar fashion.

In the ox the short lateral ligaments are well defined, a ligament connects the accessory carpal with the distal end of the ulna, and strong bands connect the distal bones with the metacarpus.

The interosseous and interordinal ligaments vary with the number of carpal bones present in the different species.

INTERMETACARPAL JOINTS

In the ox the small (fifth) metacarpal bone articulates with the large metacarpal, but not with the carpus. The joint cavity is connected with that of the carpo-metacarpal sac. The proximal end of the small metacarpal bone is attached by a ligament to the fourth carpal, and another band extends from its distal part to the side of the large metacarpal. There is also an interosseous ligament, which is permanent and allows a small amount of movement.

The chief metacarpal bones of the pig, and the second to the fifth of the dog, articulate with each other at their proximal ends, and are connected by interosseous ligaments, which do not, however, unite them closely, as in the horse.

[Illustration:

FIG. 168.—DISTAL PART OF LIMB OF OX, SHOWING LIGAMENTS AND TENDONS. ONE DIGIT AND CORRESPONDING ARTICULAR PART OF METACARPAL BONE ARE REMOVED.

(Ellenberger-Baum, Anat. d. Haustiere.)]

METACARPO-PHALANGEAL JOINTS

=Ox.=—There are two joints, one for each digit. The two capsules communicate posteriorly. The two interdigital lateral ligaments (Ligamenta collateralia interdigitalia) result from the bifurcation of a band which arises in the furrow between the divisions of the distal end of the large metacarpal bone; they spread out and end on the proximal ends of the first phalanges. A strong =superior interdigital ligament= (Ligamentum interdigitale), consisting of short intercrossing fibers, unites the middles of the interdigital surfaces of the first phalanges.

Crucial ligaments (Ligamenta phalango-sesamoideæ) connect the sesamoids with the proximal end of the opposite first phalanx.

The intersesamoid ligament connects all four sesamoids, and extends upward much less than in the horse.

The lateral sesamoidean ligaments end almost entirely on the first phalanges.

The superficial inferior sesamoidean ligament is absent. The middle inferior sesamoidean ligaments of each digit are two short strong bands which extend from the distal margins of the sesamoids to the proximal ends of the first phalanges. The deep inferior sesamoidean ligaments are strong and distinctly crucial.

[Illustration:

FIG. 169.—LIGAMENTS AND TENDONS OF DIGITS OF PIG, VOLAR VIEW.

(Ellenberger-Baum, Anat. d. Haustiere.)]

[Illustration:

FIG. 170.—LIGAMENTS AND TENDONS OF PAW OF DOG, HIND LIMB, VOLAR VIEW.

_a_, _a′_, Superficial flexor tendon; _b_, tendon to large pad; _c_, lumbricales muscles; _d_, interossei muscles; _e_, _f_, annular ligaments at metatarsophalangeal joints; _g_, suspensory ligament of large pad; _h_, digital annular ligaments; _i_, deep flexor tendon; _k_, distal sesamoid; _l_, suspensory ligament of _k_; _m_, suspensory ligament of digital pad; _n_, digital pads. (Ellenberger-Baum, Anat. d. Haustiere.)]

The suspensory or superior sesamoidean ligament is more distinctly muscular than in the horse—indeed in the young animal it consists almost entirely of muscular tissue. At the distal third of the metacarpus it divides into three branches. These give rise to five subdivisions, either by bifurcation of the lateral branches or trifurcation of the middle branch. The four lateral bands end on the sesamoid bones and the distal end of the large metacarpal bone, and detach slips to the extensor tendons. The middle band passes through the groove between the two divisions of the distal end of the metacarpus, and divides into two branches which join the tendons of the proper extensors of the digits; it sends fibers also to the interdigital lateral ligaments and to the central sesamoids. About the middle of the metacarpus the suspensory ligament detaches a band which unites lower down with the superficial flexor tendon, thus inclosing the tendon of the deep flexor of the digit; it also blends with the thick fascia of the region.

The latter gives off a band on either side to the accessory digits, and a tendinous band descends from each accessory digit to the third phalanx and sesamoid bone, blending with the tendon of the corresponding proper extensor.

=Pig.=—There are four metacarpo-phalangeal joints, each of which has a capsule, lateral, intersesamoidean, and crucial sesamoidean ligaments. Since distinct interosseous muscles are present, there are, of course, no suspensory ligaments.

=Dog.=—There are five metacarpo-phalangeal joints, each having its own capsule and indistinct lateral ligaments. A small sesamoid bone occurs in the anterior part of each capsule, over which the corresponding extensor tendon plays. The intersesamoidean ligaments do not extend above the sesamoids. The cruciate ligaments are present, as well as a fibrous layer which attaches the distal margins of the sesamoids to the posterior surface of the proximal end of the first phalanx.

INTERPHALANGEAL JOINTS

=Ox.=—The two proximal joints have separate capsules, and broad, but rather indistinct, lateral ligaments. Each joint has also two central and two lateral volar ligaments. The central ligaments are largely fused to form a strong band. The lateral ones extend from the borders of the first phalanx to the proximal end of the second phalanx.

The distal interphalangeal joints have, in addition to the capsules and lateral ligaments, bands which reinforce them on either side. The central or interdigital pair arise in the depressions on the distal ends of the first phalanges, receive fibers from the second phalanges, and end on the interdigital surfaces of the third phalanges at the margin of the articular surface. The lateral pair have a similar course, but are thinner, and end on the corresponding third sesamoid. An elastic band crosses the front of the second phalanx obliquely, from the distal end of the first phalanx to the extensor process of the third phalanx.

The =crucial= or =inferior interdigital ligaments= (Ligamenta cruciata interdigitalia) are two strong bands which limit the separation of the digits. They are attached above to the lateral (or abaxial) eminences on the proximal ends of the second phalanges (blending with the lateral ligaments), cross the deep flexor tendon obliquely, and reach the interdigital space, where they intercross and blend. Most of the fibers end on the third sesamoid of the opposite side, but some are attached to the interdigital aspect of the second phalanx and the third sesamoid of the same side. In the sheep there is, instead of the foregoing, a transverse ligament which is attached on either side to the interdigital surfaces of the second and third phalanges and the third sesamoid bone. It is related below to the skin, above to a pad of fat.

=Pig.=—The interphalangeal joints of the chief digits resemble in general those of the ox. The inferior interdigital ligament resembles, however, that of the sheep, and is intimately adherent to the skin. There is, besides, a remarkable arrangement of ligaments which connect the small digits with each other and with the chief digits.

This apparatus is somewhat complex, but its chief features are as follows: A superior interdigital ligament is attached on either side to the third phalanges of the small digits, while centrally it blends with the annular ligaments of the flexor tendons behind the metacarpo-phalangeal joints of the chief digits. Two bands (central longitudinal interdigital ligaments) arise on the bases of the small digits, cross the flexor tendons obliquely downward and inward, pass through the superior interdigital ligament, and blend below with the inferior interdigital ligament. Two lateral bands (lateral longitudinal interdigital ligaments) are attached in common with the superior interdigital ligaments to the third phalanges of the small digits, and blend below with the outer part of the inferior interdigital ligament.

=Dog.=—Each joint has a capsule and two lateral ligaments. The distal joints have also two elastic =dorsal ligaments= (Ligamenta dorsalia), which extend from the proximal end of the second phalanx to the ridge at the base of the third phalanx (Fig. 133). They produce dorsal flexion of the joint, and thus raise or retract the claws when the flexor muscles relax. The distal sesamoids are represented by complementary cartilages attached to the volar margins of the articular surfaces of the third phalanges.

Three interdigital ligaments restrict the spreading apart of the digits. Two of these cross the volar surface of the proximal parts of the chief digits, _i. e._, one for the second and third, the other for the fourth and fifth; they blend with the annular ligaments on either side. The third ligament is attached on either side to the foregoing ligaments and the annular ligaments of the third and fourth digits, and curves downward centrally, ending in the large pad on the paw.

ARTICULATIONS OF THE PELVIC LIMB

SACRO-ILIAC JOINT

This joint and the pelvic ligaments present no very striking differences in the other animals. The sacro-sciatic ligament in the dog is a narrow but strong band which extends from the posterior part of the lateral margin of the sacrum to the tuber ischii; it is the homologue of the ligamentum sacro-tuberosum of man.

HIP JOINT

=Ox.=—The shallowness of the acetabulum is compensated by the greater size of the marginal cartilage. The head of the femur has a smaller radius of curvature than that of the horse, and the articular surface extends a considerable distance outward on the upper surface of the neck. The round ligament is entirely intraarticular; it is small, and sometimes absent. The pubo-femoral or accessory ligament is absent.

There are no important differences in the other animals.

STIFLE JOINT

=Ox.=—There is a considerable communication between the femoro-patellar and inner femoro-tibial joint cavities; this is situated as in the horse, but is wider. A small communication with the external femoro-tibial capsule sometimes occurs. The two femoro-tibial capsules usually communicate. The middle patellar ligament is not sunken, as there is no groove on the tuberosity of the tibia where it is attached. The external patellar ligament fuses completely with the tendon of insertion of the biceps femoris, and a synovial bursa is interposed between them and the external condyle of the femur.

In the other animals there is a single ligamentum patellæ, and the synovial sacs communicate so freely as to constitute a common joint cavity. In the dog the semilunar cartilages are united anteriorly by a transverse ligament, and the posterior part of the capsule contains the two Vesalian sesamoids, which articulate with the condyles of the femur.

TIBIO-FIBULAR JOINTS

=Ox.=—The proximal end of the fibula fuses with the external condyle of the tibia. The distal end remains separate, and forms an arthrosis with the distal end of the tibia; the movement here is imperceptible, as the two bones are closely united by strong peripheral fibers.

=Pig.=—The superior joint is provided with a capsule which is reinforced in front and behind by fibrous tissue.

The interosseous ligament attaches the shaft of the fibula to the outer border of the tibia.

The inferior joint is included in the capsule of the hock joint, and is strengthened by oblique anterior and posterior ligaments. There is also an interosseus ligament.

=Dog.=—The arrangement is essentially the same as in the pig, but there is no interosseous ligament in the inferior joint.

HOCK JOINT

=Ox.=—There is very considerable mobility at the first intertarsal joint, the capsule of which is correspondingly roomy. The short external lateral ligament is attached below on the tibial tarsal only. A strong transverse ligament attaches the external malleolus (distal end of the fibula) to the back of the tibial tarsal bone. The dorsal or oblique ligament is narrow and thin.

=Pig.=—The arrangement in general resembles that of the ox.

=Dog.=—The long lateral ligaments are very small, and the short ones double. The plantar ligament is weak, and ends on the fourth metacarpal bone. No distinct dorsal (or oblique) ligament is present. Movement occurs almost exclusively at the tibio-tarsal joint.

The remaining joints resemble those of the thoracic limb.

THE MUSCULAR SYSTEM

MYOLOGY

The =muscles= (Musculi) are the active organs of motion. They are characterized by their property of contracting when stimulated. Muscular tissue is of three kinds: (_a_) =Striated= or striped; (_b_) =non-striated=, unstriped, or smooth; and (_c_) =cardiac=. Only the first of these varieties will be considered in this section. The striped muscles, being for the most part directly or indirectly connected with the skeleton, are often termed =skeletal= or somatic, while unstriped muscle may be spoken of as =visceral= or splanchnic. The former cover the greater part of the skeleton, and thus in a large measure determine the form of the animal. They are red in color, the shade varying in different muscles and under various conditions.

Muscles vary greatly in =form=, and may be classified as—(_a_) =Long=; (_b_) =short=; (_c_) =flat=; (_d_) =ring-like= or =orbicular=. Long muscles are found chiefly in the limbs, while the flat or broad muscles occur principally in the trunk, where they assist in forming the walls of the body cavities. The ring-like or orbicular muscles circumscribe orifices which they close, and are hence termed =sphincters=.

=Attachments.=—The muscles are attached to =bones=, =cartilages=, =ligaments=, =fasciæ=, or the =skin=. In all cases the attachment is by means of fibrous tissue, the muscle-fibers not coming into direct relation with the bone or cartilage. The perimysium of the muscle may fuse directly with the periosteum or perichondrium (fleshy attachment), or the union may be by means of intermediary fibrous structures called =tendons= or =aponeuroses= (tendinous attachment). Tendons may be funicular, ribbon-like, or in the form of membranous sheets; to the latter the term aponeurosis is commonly applied.

In certain positions, especially where tendons play over joints or are subjected to great pressure, =sesamoid bones= develop in the original tendon tissue. Some of these are large and constant, as the patella and the great sesamoids of the fetlock.

The accessory structures connected with the muscles are the =synovial membranes= and the =fasciæ=.

[Illustration:

FIG. 171.—DIAGRAMS OF CROSS-SECTIONS OF TENDON SHEATH (A) AND BURSA (B); T, TENDON.]

The =synovial membranes= are arranged in two principal forms: (_a_) =Bursal=; (_b_) =vaginal=. A =bursa= (Bursa mucosa) is a simple sac interposed between the tendon or muscle and some deeper seated structure—most commonly a bony prominence. A =vagina tendinis= or =tendon sheath= differs from a bursa in the fact that the synovial sac is folded around the tendon more or less completely, so that two layers can be distinguished; of these, the inner one adheres closely to the tendon, while the outer lines the groove or canal in which the tendon lies. The two layers are continuous along a fold termed the =mesotendon=. The arrangement is shown in Fig. 171.[41] The articular synovial membranes in some places form extra-articular pouches, which facilitate the play of tendons.

The =fasciæ= are sheets of connective tissue, mainly of the white fibrous variety, with a greater or less admixture of elastic fibers in certain cases. Two layers may usually be recognized. Of these, the =superficial fascia= (Fascia subcutanea) is composed of loose connective tissue which may contain more or less fat and is subcutaneous. The =deep fascia= is composed of one or more layers of dense fibrous tissue spread over the surface of the muscles chiefly. Its deep face may be very loosely attached to the underlying structures or may fuse with the epimysium, tendons, bones, or ligaments. In some parts, especially the limbs, septal plates pass between the muscles and are attached to the bones or ligaments; these are termed =intermuscular septa=. In this way many muscles are inclosed in fibrous sheaths which hold them in position. Not uncommonly special bands stretch across the grooves in which tendons play, converting these into canals. Such bands are termed =vaginal= or =annular ligaments=. The deep fascia is often so distinctly tendinous in structure, furnishing attachment to special tensor muscles, as to render the distinction between fascia and aponeurosis quite arbitrary. Bursæ occur in certain situations between the fascia and underlying structures (subfascial bursæ), or between the fascia and the skin (subcutaneous bursæ).

It is convenient to divide the description of a muscle into seven heads, viz.: (1) Name, followed by important synonyms; (2) position and form; (3) attachments; (4) action; (5) structure; (6) relations; (7) blood and nerve supply.

1. The =name= is determined by various factors, viz.: (_a_) The action, _e. g._, extensor, adductor, etc.; (_b_) the shape, _e. g._, quadratus, triangularis; (_c_) the direction, _e. g._, rectus, obliquus; (_d_) the position, _e. g._, the subscapularis, iliacus; (_e_) the division (into heads, etc.), _e. g._, biceps, triceps, etc.; (_f_) the size, _e. g._, major, minor, etc.; (_g_) the attachments, _e. g._, sterno-cephalicus, mastoido-humeralis; (_h_) the structure, _e. g._, semitendinosus. In most cases two or more of these factors have combined to produce the name, _e. g._, adductor magnus, longus colli, obliquus externus abdominis.

2. The =shape= is, in many cases, sufficiently definite to allow the use of such terms as triangular, quadrilateral, fan-shaped, long, flat, fusiform, ring-like, etc.

3. The =attachments= are in most cases to bone, but many muscles are attached to cartilage, ligaments, fascia, the skin, etc. It is usual to apply the term =origin= to the attachment which always or more commonly remains fixed when the muscle contracts. The term =insertion= designates the movable attachment. Such a distinction cannot always be made, as the action may be reversible, or both attachments may be freely movable.

4. The =action= belongs rather to physiological study, but is briefly indicated in anatomical descriptions.

5. The =structure= includes the direction of the muscle-fibers, the arrangement of the tendons, the synovial membranes, and any other accessory structures, _e. g._, annular ligaments and reinforcing sheaths and bands. The relation of the muscle-fibers to the tendon varies, and this fact has given rise to special terms. Thus a muscle in which the fibers converge to either side of the tendon is termed =bipennate=; while one in which this arrangement exists only on one side of the tendon is called =unipennate=. The terms fleshy and tendinous are used to indicate the relative amounts of muscular and tendinous tissue. The muscular tissue is often spoken of as the =belly= (Venter) of the muscle. In the case of the long muscles, the origin is often termed the =head= (Caput). Muscles having two or more heads are called biceps, triceps, etc. =Digastric= muscles are those which have two bellies joined by an intermediate tendon. Ring-like muscles which circumscribe openings are termed =sphincters=, on account of their action.

6. The =relations= are, of course, important on surgical grounds.

7. The =nerve-supply= is of clinical interest, and is important for the determination of homologies.

FASCIÆ AND MUSCLES OF THE HORSE

PANNICULUS CARNOSUS

The =panniculus carnosus= (Musculus cutaneus) is a thin muscular layer developed in the superficial fascia. It is intimately adherent in great part to the skin, but has very little attachment to the skeleton. It does not cover the entire body, and may be conveniently divided into facial, cervical, thoracic, and abdominal portions, each of which will be described with the muscles of the corresponding region.

THE FASCIÆ AND MUSCLES OF THE HEAD

The muscles of the head may be divided into three groups, viz.: (1) Superficial muscles, including the panniculus and those of the lips, cheeks, nostrils, eyelids, and external ear; (2) the orbital muscles; (3) the muscles of mastication.

The =superficial fascia= forms an almost continuous layer, but is very scanty around the natural orifices. It contains a number of the thin superficial muscles, so that care must be exercised in removing the skin. Over the frontal and nasal bones the fascia blends with the periosteum.

The =deep fascia= is of special interest in three regions. The =temporal fascia= covers the temporalis muscle, and is attached to the parietal and frontal crests internally, and to the zygomatic arch externally. The =buccal fascia= covers the buccinator muscle and the free part of the outer surface of the ramus of the jaw. Superiorly it is attached to the facial crest, and posteriorly it forms a band (Ligamentum pterygomandibulare) which stretches from the hamulus of the pterygoid bone to the mandible behind the last molar tooth. It is directly continuous with the =pharyngeal fascia=, which is attached to the great and thyroid cornua of the hyoid bone, covers the lateral walls of the pharynx, and blends dorsally with the median raphé of the constrictor muscles of the latter.

SUPERFICIAL MUSCLES

1. =Panniculus carnosus.=—The facial panniculus (M. cutaneus faciei) consists of a thin and usually incomplete muscular stratum, which covers the submaxillary space and the masseter muscle. A branch from it passes forward to the angle of the mouth and blends with the orbicularis oris; this part (M. cutaneus labiorum) retracts the angle of the mouth. (A number of the superficial muscles of the face may be considered modified parts of the panniculus, _e. g._, the corrugator supercilii, malaris, zygomaticus, etc.)

MUSCLES OF THE LIPS AND CHEEKS

1. =Orbicularis oris.=—This is the sphincter muscle of the mouth; it is continuous with the other muscles which converge to the lips. It lies between the skin and the mucous membrane of the lips, and is intimately adherent to the former. Most of the fibers run parallel to the free edges of the lips and have no direct attachment to the skeleton.

Action.—It closes the lips.

Blood-supply.—Palato-labial, facial, and mental arteries.

Nerve-supply.—Facial nerve.

[Illustration:

FIG. 172.—MUSCLES OF HEAD OF HORSE, LATERAL VIEW. THE PANNICULUS IS REMOVED.

_a_, Levator labii superioris proprius; _b_, levator nasolabialis; _c_, mastoido-humeralis; _d_, sterno-cephalicus; _d′_, tendon of _d_; _e_, omo-hyoideus; _f_, dilatator naris lateralis; _g_, zygomaticus; _h_, buccinator; _i_, depressor labii inferioris; _k_, orbicularis oris; _l_, dilatator naris superior; _m_, masseter; _n_, parotido-auricularis; _o_, zygomatico-auricularis; _p_, interscutularis; _p′_, fronto-scutularis, pars temporalis; _q_, cervico-auricularis profundus major; _r_, cervico-auricularis superficialis; _s_, obliquus capitis anterior; _t_, splenius; v, stylo-maxillaris; _y_, mastoid tendon of mastoido-humeralis; _2_, posterior, _3_, anterior, border of external ear; _8_, scutiform cartilage; _9_, zygomatic arch; _10_, depression behind supraorbital process; _18_, temporo-mandibular articulation; _27_, facial crest; _30′_, angle of jaw; _37_, external maxillary vein; _38_, jugular vein; 39, facial vein; _40_, parotid duct; _41_, transverse facial vein; _42_, masseteric vein; _43_, facial nerve; _44_, parotid gland; _45_, chin; _x_, wing of atlas. (After Ellenberger-Baum, Anat. für Künstler.)]

2. =Levator nasolabialis= (Levator labii superioris alæque nasi).—This thin muscle lies directly under the skin, and chiefly on the lateral surface of the nasal region.

Origin.—The frontal and nasal bones.

Insertion.—(1) The upper lip and the outer wing of the nostril; (2) the commissure of the lips.

Action.—(1) To elevate the upper lip and the commissure; (2) to dilate the nostril.

Structure.—The muscle arises by a thin aponeurosis. The belly is also thin, and divides into two branches, between which the lateral dilator of the nostril passes. The dorsal branch reaches the nostril and upper lip, blending with the lateral dilator; the ventral one is much smaller, and blends at the labial commissure with the orbicularis and buccinator.

Relations.—Superficially, the skin, fascia, and lateral dilator (in part); deeply, the levator labii superioris proprius, lateral dilator (in part), buccinator, branches of the facial vessels and nerve, and the infraorbital artery and nerve.

Blood-supply.—Facial and palato-labial arteries.

Nerve-supply.—Facial nerve.

[Illustration:

FIG. 173.—MUSCLES OF HEAD OF HORSE, DORSAL VIEW. THE PANNICULUS IS REMOVED.

_a_, Levator labii superioris proprius; _a′_, common tendon of a with opposite muscle; _b_, levator nasolabialis; _f_, dilatator naris lateralis; _g_, zygomaticus; _l_, dilatator naris superior; _n_, parotido-auricularis; _o″_, scutulo-auricularis superficialis superior; _p_, interscutularis; _p′_, fronto-scutularis, pars temporalis; _r_, cervico-auricularis superficialis; _u_, corrugator supercilii; _x_, transversus nasi; _2_, posterior, _3_, anterior, border of external ear; _8_, scutiform cartilage; _9_, zygomatic arch; _10_, supraorbital depression; _35_, inner wing of nostril, containing lamina of alar cartilage; _39_, facial vein. (After Ellenberger-Baum, Anat. für Künstler.)]

3. =Levator labii superioris proprius.=—This lies on the dorso-lateral aspect of the face, partly covered by the preceding muscle.

Origin.—The lacrimal, malar, and maxillary bones at their junction.

Insertion.—The upper lip, by a common tendon, with its fellow.

Action.—Acting with its fellow, to elevate the upper lip. This action, if carried to the fullest extent, results in eversion. In unilateral action the lip is drawn upward and to the side of the muscle acting.

Structure.—The muscle has a short, thin tendon of origin. The belly is at first flattened, but becomes narrower and thicker, then tapers over the false nostril, to terminate in a tendon. The tendons of the two muscles unite over the alar cartilages of the nostrils, forming an expansion which spreads out in the substance of the upper lip.

Relations.—Superficially, the skin, the levator nasolabialis, and the angular vessels of the eye; deeply, the superior and transverse dilators of the nostril and the infraorbital artery and nerve.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

4. =Zygomaticus.=—This very thin muscle lies immediately under the skin of the cheek.

Origin.—The fascia covering the masseter muscle below the facial crest.

Insertion.—The commissure of the lips, blending with the buccinator.

Action.—To retract and raise the angle of the mouth.

Structure.—Fleshy, with a thin aponeurotic origin.

Relations.—Superficially, the skin; deeply, the buccinator.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

5. =Incisivus superior= (Depressor labii superioris).—This lies under the mucous membrane of the upper lip.

Origin.—The alveolar border of the premaxilla from the second incisor to the first cheek tooth.

Insertion.—The upper lip.

Action.—To depress the upper lip.

6. =Incisivus inferior.=—This is arranged in the lower lip like the preceding muscle in the upper one.

Origin.—The alveolar border of the mandible from the second incisor to a point near the first cheek tooth.

Insertion.—The skin of the lower lip and the prominence of the chin.

Action.—To raise the lower lip.

7. =Mentalis= (Levator menti).—This is situated in the prominence of the chin. Its fibers arise from each side of the body of the mandible and are inserted into the skin of the chin. It is mingled with fat and strands of connective tissue, in which the roots of the tactile hairs are embedded. It raises and corrugates the skin to which it is attached.

8. =Depressor labii inferioris.=—This muscle lies on the outer surface of the ramus of the mandible, along the ventral border of the buccinator.

Origin.—The alveolar border of the mandible near the coronoid process and the maxillary tuberosity, in common with the buccinator.

Insertion.—The lower lip.

Action.—To depress and retract the lower lip.

Structure.—The tendon of origin and the belly are fused with the buccinator as far forward as the first cheek tooth. From this point forward the belly is distinct and rounded, terminating in a tendon which spreads out in the lower lip, blending with the orbicularis and the muscle of the opposite side.

Relations.—Superficially, the skin, masseter, facial vessels, and parotid duct; deeply, the mandible and inferior labial artery.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

9. =Buccinator.=—This muscle lies in the lateral wall of the mouth, extending from the angle of the mouth to the maxillary tuberosity.

Origin.—The external surface of the maxilla above the interdental space and the molar teeth; the alveolar border of the mandible at the interdental space and also posteriorly where it turns upward to the coronoid process; the pterygo-mandibular ligament.

Insertion.—The angle of the mouth, blending with the orbicularis oris.

Action.—To flatten the cheeks, thus pressing the food between the teeth; also to retract the angle of the mouth.

Structure.—Two layers may be recognized. The =superficial layer= (Pars buccalis) extends from the angle of the mouth to the masseter. It is incompletely pennate, having a longitudinal raphé on which most of the muscle-fibers converge. The upper fibers are directed chiefly downward and backward, the lower ones upward and backward. The =deep layer= (Pars molaris) consists mainly of longitudinal fibers. It blends in part with the superficial layer of the orbicularis; it has a small tendinous attachment to the coronoid process behind, and is united below with the depressor labii inferioris.

Relations.—Superficially, the skin and fascia, the zygomaticus, levator nasolabialis, lateral dilator of the nostril, the superior buccal glands, the parotid duct, the facial vessels, and branches of the facial nerve; deeply, the mucous membrane of the mouth and the inferior buccal glands.

Blood-supply.—Facial and buccinator arteries.

Nerve-supply.—Facial nerve.

MUSCLES OF THE NOSTRILS

1. =Levator nasolabialis.=—This has been described (p. 214).

2. =Dilatator naris lateralis= (M. caninus).—This thin, triangular muscle lies on the lateral nasal region, and passes between the two branches of the levator nasolabialis.

Origin.—The maxilla, close to the anterior extremity of the facial crest.

Insertion.—The outer wing of the nostril.

[Illustration:

FIG. 174.—NASAL AND SUPERIOR LABIAL MUSCLES OF HORSE.

_a_, _a′_, Dilatator naris transversus; _b_, levator labii superioris proprius; _b′_, tendon of _b_; _b″_, common tendon of two levatores labii superioris proprii; _c_, _c′_, dilatator naris inferior; _d_, _e_, dilatator naris superior; _f_, orbicularis oris; _g_, levator nasolabialis, a portion of which is removed; _h_, dilatator naris lateralis (cut); _i_, cornu of alar cartilage; _k_, nostril; _k′_, false nostril; _l_, nasal diverticulum; _m_, nasal bone. (After Ellenberger-Baum, Top. Anat. d. Pferdes.)]

Action.—To dilate the nostril.

Structure.—The muscle has a flat tendon of origin, passes between the two branches of the levator nasolabialis, and spreads out in the external wing of the nostril. The lower fibers blend with the orbicularis oris.

Relations.—Superficially, the skin, fascia, and the labial branch of the levator nasolabialis; deeply, the maxilla and the nasal branch of the levator nasolabialis.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

3. =Dilatator naris transversus= (M. transversus nasi).—This is an unpaired, quadrilateral muscle, which lies between the nostrils. It consists of two layers.

Attachments.—Superficial layer, the superficial faces of the laminæ of the alar cartilages; deep layer, the convex edges of the cornua of the same.

Action.—To dilate the nostrils.

Structure.—It is composed of transverse fleshy fibers, which blend below with the orbicularis.

Relations.—Superficially, the skin, fascia, and tendinous expansion of the levator labii superioris proprius; deeply, the alar cartilages, the extremity of the septum nasi, and the palato-labial artery.

Blood-supply.—Palato-labial artery.

Nerve-supply.—Facial nerve.

4. =Dilatator naris superior= (Pars dorsalis m. lateralis nasi).—This very thin muscle occupies the angle between the nasal process of the premaxilla and the nasal bone.

Origin.—The lateral border of the nasal bone.

Insertion.—The inner wall of the false nostril and the parietal lamina of the septal cartilage.

Action.—To dilate the vestibule of the nasal cavity.

Structure.—Fleshy.

Relations.—Superficially, the skin, fascia, and levator labii superioris proprius; deeply, the parietal cartilage and false nostril.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

5. =Dilatator naris inferior= (Pars ventralis m. lateralis nasi).—This is a similar but thicker muscle, which lies on the nasal process of the premaxilla.

Origin.—The maxilla and the nasal process of the premaxilla.

Insertion.—The cartilaginous prolongations of the turbinal bones and the inner wall of the false nostril.

Action.—To rotate the turbinal outward and dilate the nostril and the vestibule of the nasal cavity.

Structure.—Fleshy. A division into two or more parts may be recognized. A small part posteriorly is inserted into the cartilage of the dorsal turbinal bone, while the bulk of the muscle is inserted into the cartilage of the ventral turbinal bone. A few fibers also pass between the cornu of the alar cartilage and the outer wing of the nostril.

Relations.—Superficially, the levator labii superioris proprius, the levator nasolabialis, and the lateral nasal artery; deeply, the maxilla, the premaxilla, and the anterior nasal branch of the infraorbital nerve.

Blood-supply.—Facial artery.

Nerve-supply.—Facial nerve.

MUSCLES OF THE EYELIDS

1. =Orbicularis oculi.=—This is a flat, elliptical, sphincter muscle, situated in and around the eyelids, the portion in the upper lid being much broader than that in the lower. The chief attachment is to the skin of the lids, but some bundles are attached to the palpebral ligament at the inner canthus and to the lacrimal bone. Its action is to close the lids.

2. =Corrugator supercilii.=—This is a very thin, small muscle, which arises over the root of the supraorbital process and spreads out in the upper eyelid, blending with the orbicularis. Its action is to assist in raising the upper lid or, especially in pathological conditions, to wrinkle the skin.

3. =Malaris.=—This is a very thin muscle, which varies much in different subjects. It extends from the fascia in front of the orbit to the lower lid. Its action is to depress the lower lid.

The foregoing muscles receive their blood-supply from the facial, transverse facial, supraorbital, and infraorbital arteries; the nerve-supply is derived from the facial nerve.

4. =Levator palpebræ superioris.=—This slender, flat muscle is almost entirely within the orbital cavity. It arises on the pterygoid crest, passes forward above the rectus oculi superior and below the lacrimal gland, and terminates in a thin tendon in the upper lid.

Action.—To elevate the upper lid.

Blood-supply.—Ophthalmic artery.

Nerve-supply.—Oculomotor nerve.

MUSCLES OF MASTICATION

The muscles of this group are six in number in the horse. They arise chiefly from the upper jaw and the base of the cranium, and are all inserted into the mandible.

1. =Masseter.=—This muscle extends from the zygomatic arch and facial crest over the broad part of the mandibular ramus. It is semi-elliptical in outline.

Origin.—By a strong tendon from the zygomatic arch and the facial crest.

Insertion.—The outer surface of the broad part of the ramus of the mandible.

Action.—Its action is to bring the jaws together. Acting singly, it also carries the lower jaw toward the side of the contracting muscle.

Structure.—The superficial face of the muscle in its upper part is covered by a strong, glistening aponeurosis, and several tendinous intersections partially divide the muscle into layers. The fibers of the superficial layer take origin from the malar and maxilla only, and diverge somewhat to their insertion close to the thick ventral border of the lower jaw. The fibers of the deep layer arise from the entire area of origin, and pass straight to the border of the mandible; it will be noted that a small part, near the temporo-maxillary joint, is not covered by the superficial layer. The two layers are separable only above and behind; elsewhere they are fused.

Relations.—Superficially, the skin and panniculus, the parotid gland, the transverse facial and masseteric vessels, and the facial nerve; deeply, the ramus of the mandible, the buccinator, depressor labii inferioris, and mylo-hyoideus muscles, the superior buccal glands, the buccinator nerve, and two large varicose veins which join the facial vein at the anterior edge of the muscle. The facial vessels and parotid duct run along the anterior edge of the muscle; the duct, however, bends forward about the middle of the border and leaves the muscle.

Blood-supply.—Transverse facial and masseteric arteries.

Nerve-supply.—Mandibular nerve.

2. =Temporalis.=—This muscle occupies the temporal fossa.

Origin.—The rough part of the temporal fossa and the crests which surround it.

Insertion.—The coronoid process of the mandible, which it envelops.

Action.—Chiefly to raise the lower jaw, acting with the masseter and internal pterygoid muscles.

Structure.—The surface of the muscle is covered with a glistening aponeurosis, and strong tendinous intersections are found in its substance. The inner edge of the muscle is quite thin, but as the fibers converge toward the much smaller area of insertion, the muscle becomes nearly an inch thick. It fuses somewhat with the masseter.

Relations.—Superficially, the scutiform cartilage and anterior muscles of the external ear and the orbital fat; deeply, the temporal fossa and the deep temporal vessels and nerves.

Blood-supply.—Superficial and deep temporal, and mastoid arteries.

Nerve-supply.—Mandibular nerve.

3. =Pterygoideus internus= (s. medialis).—This muscle occupies a position on the inner surface of the ramus of the mandible similar to that of the masseter on the outside.

Origin.—The crest formed by the pterygoid process of the sphenoid and the palate bone.

Insertion.—The concave inner surface of the broad portion of the ramus of the mandible, and the inner lip of the lower border.

Action.—Acting together, to raise the lower jaw; acting singly, to produce also lateral movement of the jaw.

Structure.—The muscle is capable of division into two parts. The principal part is superficial (internal), and its fibers are, for the most part, vertical in direction. It contains much tendinous tissue (septa). The smaller portion is external to the foregoing, and its fibers are directed downward and backward.

[Illustration:

FIG. 175.—SAGITTAL SECTION OF HEAD OF HORSE, SHOWING DEEP PTERYGO-MAXILLARY REGION, AND NASAL AND CRANIAL CAVITIES.

_1_, Cerebral compartment of cranial cavity; _2_, cerebellar compartment of same; _3_, tentorium osseum; _4_, tentorium cerebelli; _5_, sphenoidal sinus; _6_, hamulus of pterygoid bone-tendon of tensor palati cut off short at anterior border of hamulus; _7_, mylo-glossus. The olfactory mucous membrane is shaded.]

Relations.—Externally, the ramus of the mandible, the external pterygoid muscle, the inferior alveolar vessels and nerve, and the lingual and mylo-hyoid nerves; internally, the great cornu of the hyoid bone, the tensor palati, pterygo-pharyngeus, palato-pharyngeus, mylo-hyoideus, digastricus, and stylo-hyoideus muscles, the guttural pouch, the external maxillary vessels, the ninth and twelfth nerves, the submaxillary salivary gland, the submaxillary and parotid ducts, and the submaxillary and pharyngeal lymph glands.

Blood-supply.—Internal maxillary, masseteric, and inferior alveolar arteries.

Nerve-supply.—Mandibular nerve.

4. =Pterygoideus externus= (=s. lateralis=).—This muscle is considerably smaller than the preceding one, and is situated external to its upper part.

Origin.—The external surface of the pterygoid process of the sphenoid bone.

Insertion.—The inner surface of the neck and the inner part of the anterior border of the condyle of the mandible.

Action.—Acting together, to draw the lower jaw forward; acting singly, to move the jaw laterally, _i. e._, toward the side opposite to the muscle acting. The latter action is due to the fact that the origin is nearer to the median plane than the insertion.

[Illustration:

FIG. 176.—SUBMAXILLARY AND LARYNGEAL REGIONS OF HORSE, AFTER REMOVAL OF SKIN AND PANNICULUS.

_c_, Mastoido-humeralis; _d_, sterno-cephalicus; _e_, omo-hyoideus and sterno-hyoideus; _h_, buccinator; _i_, depressor labii inferioris; _m_, masseter; _v_, stylo-maxillaris; _w_, mylo-hyoideus; _2_, posterior, _3_, anterior, border of external ear; _30′_, angle of jaw; _36_, submaxillary lymph glands; _37_, external maxillary vein; _39_, facial continuation of _37_; _40_, parotid duct; _44_, parotid gland; _45_, prominence of chin; _x_, wing of atlas. (After Ellenberger-Baum, Anat. für Künstler.)]

Structure.—The muscle is almost entirely fleshy, and the fibers are almost longitudinal in direction. Some of them are inserted into the edge of the interarticular meniscus.

Relations.—Externally, the temporo-maxillary articulation and the temporalis muscle; internally, the internal pterygoid and tensor palati muscles. The internal maxillary artery crosses the lower face of the muscle and dips in between it and the tensor palati. The mandibular nerve lies on the ventral surface, and the buccinator nerve perforates the origin of the muscle.

Blood-supply.—Internal maxillary and inferior alveolar arteries.

Nerve-supply.—Mandibular nerve.

5. =Stylo-maxillaris= (s.-mandibularis) (M. jugulomandibularis).—This is a short muscle extending from the paramastoid or styloid process of the occipital bone to the posterior border of the lower jaw; it is covered by the parotid gland.

Origin.—The paramastoid or styloid process of the occipital bone, in common with the posterior belly of the digastricus.

Insertion.—The posterior border of the ramus of the mandible.

Action.—To depress the lower jaw and open the mouth.

Structure.—The muscle contains a good deal of tendinous tissue. It blends with the posterior belly of the digastricus.

Relations.—Superficially, the parotid gland, the tendon of the sterno-cephalicus, and the fibrous expansion which connects it with the tendon of the mastoido-humeralis; deeply, the guttural pouch, the external carotid artery, the ninth and twelfth nerves, the pharynx, and the submaxillary gland.

Blood-supply.—External carotid artery.

Nerve-supply.—Facial nerve.

6. =Digastricus.=—This muscle is composed of two fusiform, flattened bellies, united by a round tendon.

Origin.—The paramastoid or styloid process of the occipital bone, in common with the preceding muscle.

Insertion.—The inner surface of the lower border of the mandible behind the symphysis.

Action.—It assists in depressing the lower jaw and opening the mouth. If the mandible be fixed and both bellies contract, the hyoid bone and the base of the tongue are raised, as in the first phase of deglutition.

Structure.—The posterior belly has the appearance of a branch detached from the inner surface of the stylo-maxillaris. It passes downward and forward, and is succeeded by a small rounded tendon. The latter perforates the tendon of insertion of the stylo-hyoideus, and is provided with a =synovial sheath=. The anterior belly is larger and terminates by thin tendinous bundles.

Relations.—The posterior belly has practically the same relations as the stylo-maxillaris. The intermediate tendon is in contact externally with the internal pterygoid muscle, the submaxillary gland and duct, and the external maxillary artery. The anterior belly lies in the submaxillary space between the ramus of the jaw and the mylo-hyoideus muscle; the sublingual vessels run along its upper border.

Blood-supply.—External carotid and sublingual arteries.

Nerve-supply.—Facial and mandibular nerves.

THE HYOID MUSCLES

This group consists of eight muscles, one of which, the hyoideus transversus, is unpaired.

1. =Mylo-hyoideus.=—This muscle, together with its fellow, forms a sort of sling between the two rami of the lower jaw, in which the tongue is supported.

Origin.—The inner surface of the alveolar border of the mandible.

Insertion.—(1) A median fibrous raphé extending from the symphysis to the hyoid bone; (2) the lingual process and body of the hyoid bone.

Action.—It raises the floor of the mouth, the tongue, and the hyoid bone.

Structure.—Each muscle consists of a thin curved sheet, the fibers passing downward from their origin and then curving toward the median raphé. It is chiefly fleshy, and is thickest behind. The anterior superficial part of the muscle is termed the mylo-glossus.

Relations.—On the superficial surface of the muscles are the ramus, the internal pterygoid and digastricus muscles, and the submaxillary lymph glands. The deep surface is in contact with the mucous membrane of the mouth, the stylo-glossus, hyo-glossus, and genio-hyoideus muscles, the sublingual gland and vessels, the submaxillary duct, and the lingual and hypoglossal nerves.

Blood-supply.—Sublingual artery.

Nerve-supply.—Mylo-hyoid branch of the mandibular nerve.

2. =Stylo-hyoideus.=—This is a slender, fusiform muscle, having a direction nearly parallel to that of the great cornu of the hyoid bone (Fig. 436).

Origin.—The heel-like prominence on the proximal extremity of the great cornu of the hyoid bone.

Insertion.—The anterior part of the thyroid cornu of the hyoid bone.

Action.—It draws the base of the tongue and the larynx upward and backward.

Structure.—It arises by a thin, short tendon, and has a fusiform belly. The tendon of insertion is perforated for the passage of the intermediate tendon of the digastricus, and at this point there is a small synovial sheath.

Relations.—Superficially, the internal pterygoid muscle and the parotid gland; deeply, the guttural pouch, the pharynx, the external carotid and maxillary arteries, and the hypoglossal nerve.

Blood-supply.—External carotid artery.

Nerve-supply.—Facial nerve (stylo-hyoid branch).

3. =Occipito-hyoideus= (M. jugulo-hyoideus; occipito-styloideus).—This is a small triangular muscle, which lies in the space between the paramastoid process and the great cornu of the hyoid bone.

Origin.—The paramastoid (styloid) process of the occipital bone.

Insertion.—The proximal extremity and ventral edge of the great cornu of the hyoid bone.

Action.—It carries the distal extremity of the great cornu backward and upward. Acting with the genio-hyoideus and digastricus, it raises the hyoid bone and the larynx.

Structure.—The muscle is somewhat triangular, its fibers being longer as the ventral border is approached. It blends with the posterior belly of the digastricus.

Relations.—Superficially, the parotid gland; deeply, the guttural pouch.

Blood-supply.—Occipital artery.

Nerve-supply.—Facial nerve.

4. =Genio-hyoideus.=—This is a long, spindle-shaped muscle, which lies under the tongue in contact with its fellow of the opposite side (Fig. 243).

Origin.—The angle of union of the rami of the mandible.

Insertion.—The extremity of the lingual process of the hyoid bone.

Action.—It draws the hyoid bone and tongue forward.

Structure.—The muscle arises by a short tendon, which is succeeded by the belly, composed of long bundles of parallel fibers.

Relations.—Below, the mylo-hyoideus; above, the hyo-glossus, stylo-glossus, genio-glossus, the sublingual gland, submaxillary duct, and the lingual nerve.

Blood-supply.—Sublingual artery.

Nerve-supply.—Hypoglossal nerve.

5. =Kerato-hyoideus.=—This small triangular muscle lies in the space between the thyroid and small cornu, under cover of the hyo-glossus (Fig. 243).

Origin.—The posterior edge of the small cornu and the adjacent part of the ventral border of the great cornu.

Insertion.—The dorsal edge of the thyroid cornu.

Action.—It raises the thyroid cornu and the larynx.

Relations.—The muscle is crossed outwardly by the lingual artery.

Blood-supply.—Lingual artery.

Nerve-supply.—Glosso-pharyngeal nerve.

6. =Hyoideus Transversus.=—This is a thin, unpaired muscle, which extends transversely between the two small cornua of the hyoid bone.

Attachments.—The small cornua close to the junction with the great cornua.

Action.—When relaxed, its upper surface is concave; when it contracts, it elevates the root of the tongue.

Structure.—Fleshy, composed of parallel transverse bundles.

Blood-supply.—Lingual artery.

Nerve-supply.—Glosso-pharyngeal nerve.

7. =Sterno-thyro-hyoideus=, and

8. =Omo-hyoideus.=—These are described with the muscles on the ventral surface of the neck.

THE FASCIÆ AND MUSCLES OF THE NECK

It is convenient to divide the muscles of the neck into ventral and lateral groups, the two lateral groups being separated from each other by the ligamentum nuchæ.

THE FASCIÆ OF THE NECK

The =superficial fascia= is in part two-layered, and contains the cervical portion of the panniculus. The fasciæ of the right and left sides are attached along the dorsal line of the neck to the ligamentum nuchæ, while along the ventral line they meet in a fibrous raphé. A deep layer is detached which passes underneath the panniculus, bridges over the jugular furrow, and crosses over the deep face of the mastoido-humeralis and omo-hyoideus to join the superficial layer. It again separates to pass under the cervical trapezius, and become attached to the ligamentum nuchæ. Along the ventral line a septum is detached which separates the sterno-cephalici. Two other layers in front of the shoulder inclose the prescapular lymph glands.

The =deep fascia= also forms two layers. The =superficial layer= is attached to the wing of the atlas and the lower edge of the trachelo-mastoideus and scalenus. Passing downward, it incloses the trachea, and, together with the deep layer, furnishes sheaths for the vagus and sympathetic nerves and the carotid artery. Passing upward it detaches septa between the extensor muscles of the spine. Anteriorly it covers the thyroid gland, the guttural pouch, the adjacent vessels and nerves and the larynx, and is attached to the mastoid process of the temporal bone and the thyroid cornu of the hyoid bone. Posteriorly, it is attached to the first rib and the cariniform cartilage of the sternum. The =deep layer= (prevertebral fascia) covers the ventral surface of the longus colli, and incloses the trachea and œsophagus. Anteriorly, it forms, with the corresponding layer of the opposite side, a septum between the guttural pouches; posteriorly, it becomes continuous with the endothoracic fascia. A =fascia propria= forms a tubular sheath around the trachea, inclosing also the recurrent nerves.

VENTRAL MUSCLES

This group consists of eleven pairs of muscles which lie almost entirely ventral to the vertebræ.

1. =Panniculus carnosus.=—The =cervical panniculus= (platysma myoides of man) has a fleshy origin on the cariniform cartilage (manubrium) of the sternum. it passes forward, outward, and upward, crossing over the sterno-cephalicus and jugular furrow obliquely. On reaching the surface of the mastoido-humeralis it adheres closely to this muscle, and soon thins out, to be continued over the splenius and trapezius by an aponeurosis which is difficult to remove from the latter muscle. Scattered bundles may be traced on the ventral surface of the neck to the facial portion. The right and left muscles meet at a ventral median raphé in pennate fashion.

[Illustration:

FIG. 177.—ANTERO-LATERAL VIEW OF MUSCLES AND SKELETON OF HORSE.

_a_, Trapezius; _c_, mastoido-humeralis; _d_, sterno-cephalicus; _f_, long head of triceps; _f′_, external head of triceps; _g_, anterior superficial pectoral muscle; _g′_, posterior superficial pectoral; _h′_, anterior deep pectoral; _v_, cervical panniculus; _z_, supraspinatus; _29_, omo-hyoideus; _30_, sterno-thyro-hyoideus; _31_, jugular vein; _32_, cephalic vein; _1_, scapula; _1′_, cartilage of scapula; _2_, spine of scapula; _4_, shaft of humerus; _4′_, external epicondyle; _5_, external tuberosity of humerus; _6_, deltoid tuberosity; _14_, ventral border (“keel”) of sternum; _14′_, cariniform cartilage; l.R., first rib. (After Ellenberger-Baum, Anat. für Künstler.)]

2. =Mastoido-humeralis.=—This is described on p. 252.

3. =Sterno-cephalicus= (Sterno-maxillaris s.-mandibularis).[42]—This is a long, narrow muscle, extending along the ventral and lateral aspects of the trachea from the sternum to the angle of the jaw. It forms the ventral boundary of the jugular furrow.

Origin.—The cariniform cartilage of the sternum.

Insertion.—The posterior border of the lower jaw.

Action.—Acting together, to flex the head and neck; acting singly, to incline the head and neck to the side of the muscle contracting.

Structure.—The two muscles are fused at their origin, which is fleshy. Near the middle of the neck they separate, and, becoming thinner, each muscle passes under the parotid gland and terminates in a flat tendon.

Relations.—Superficially, the cervical panniculus; deeply, the sterno-thyro-hyoideus and omo-hyoideus muscles. The upper edge of the muscle is related to the jugular vein, which lies in the jugular furrow. The carotid artery, the vagus, sympathetic, and recurrent nerves also lie along the upper edge at the root of the neck. The tendon passes under the submaxillary vein and the parotid gland, having the submaxillary gland and stylo-maxillaris muscle on its inner side.

Blood-supply.—Carotid artery.

Nerve-supply.—Ventral branches of the spinal accessory and first cervical nerves.

4. =Sterno-thyro-hyoideus= (Sterno-thyroideus et sterno-hyoideus).—This is a long, slender, digastric muscle, applied to the ventral surface of the trachea and its fellow of the opposite side.

Origin.—The cariniform cartilage of the sternum.

Insertion.—(1) The external surface of the thyroid cartilage of the larynx; (2) the body of the hyoid bone.

Action.—To depress and retract the hyoid bone, the base of the tongue, and the larynx, as in deglutition. It may also fix the hyoid bone when the depressors of the tongue are acting, as in suction.

Structure.—The origin of the muscle is fleshy, and as far as the middle of the neck it blends with its fellow. The common belly is then interrupted by a tendon, or sometimes two tendons, from which arise three or four fleshy bands. The lateral bands diverge to reach their insertion into the thyroid cartilage; while the inner bands, closely applied to each other and blending with the omo-hyoideus, pass straight forward to reach the ventral surface of the hyoid bone.

Relations.—At the root of the neck the common belly has the sterno-cephalicus below, and the carotid arteries and recurrent nerves above. Further forward the trachea becomes the upper relation, and near the head the skin and fascia, the lower one.

Blood-supply.—Carotid artery.

Nerve-supply.—Ventral branch of the first cervical nerve.

5. =Omo-hyoideus= (Subscapulo-hyoideus).—This is a thin, ribbon-like muscle, almost entirely fleshy, which crosses the trachea very obliquely under cover of the mastoido-humeralis.

Origin.—The subscapular fascia close to the shoulder joint.

Insertion.—The body of the hyoid bone, in common with the hyoid branch of the preceding muscle.

Action.—To depress the hyoid bone.

Structure.—The muscle is composed of parallel fleshy fibers, except at its origin, where it has a thin tendon.

Relations.—In the first part of its course the muscle passes forward between the supraspinatus, anterior deep pectoral, mastoido-humeralis (outwardly), and the scalenus (inwardly). It is intimately adherent to the mastoido-humeralis. In the middle of the neck it is related superficially to the mastoido-humeralis, sterno-cephalicus, and the jugular vein; deeply, to the rectus capitis anterior major, the carotid artery, the vagus, sympathetic, and recurrent nerves, the trachea, and, on the left side, the œsophagus. In its anterior part the muscle blends with the hyoid part of the sterno-thyro-hyoideus, the two covering the thyroid portion of the latter muscle, the thyroid gland, and the ventral face of the larynx.

Blood-supply.—Carotid and inferior cervical arteries.

Nerve-supply.—Ventral branches of the cervical nerves.

6. =Scalenus= (M. scalenus primæ costæ).—This muscle is deeply situated on the side of the posterior half of the neck. It is composed of two parts, between which the roots of the brachial plexus of nerves emerge.

Origin.—The anterior border and outer surface of the first rib.

Insertion.—(1) The dorsal (smaller) portion is attached to the transverse process of the seventh cervical vertebra; (2) the ventral portion is attached to the transverse processes of the sixth, fifth, and fourth cervical vertebræ.

Action.—The neck is flexed or inclined laterally, according as the muscles act together or singly. If the neck be the fixed point, the muscle may have a respiratory action by pulling forward or fixing the first rib.

Structure.—The dorsal portion is composed of three or four fleshy bundles.[43] The ventral portion, which is much larger, is almost entirely fleshy, and not so divided.

Relations.—Superficially, the anterior deep pectoral, mastoido-humeralis, and omo-hyoideus muscles, the phrenic nerve, and the other branches of the brachial plexus; deeply, the vertebræ, the longus colli and intertransversales muscles, the œsophagus (on the left side), the trachea (on the right side), the vertebral vessels, the vagus, sympathetic, and recurrent nerves. The roots of the brachial plexus form a flat anastomosis, which lies between the two portions of the muscle. The brachial vessels cross the ventral edge close to the first rib.

Blood-supply.—Carotid, vertebral, and inferior cervical arteries.

Nerve-supply.—Ventral branches of the cervical nerves.

7. =Rectus capitis anterior major= (M. longus capitis).—This is the largest of the three special flexors of the head, and lies along the ventro-lateral surface of the anterior cervical vertebræ and the base of the cranium.

Origin.—The transverse processes of the fifth, fourth, and third cervical vertebræ.

Insertion.—The tubercles at the junction of the basilar process of the occipital bone with the body of the sphenoid.

Action.—Acting together, to flex the head; acting singly, to incline it to the same side also.

Structure.—The origin of the muscle is by fleshy digitations. The belly increases in size by the union of these digitations, reaching its maximum at the axis. It then diminishes, passes toward the median plane, and terminates on a rounded tendon.

Relations.—Superficially, the mastoido-humeralis, omo-hyoideus, and rectus capitis anticus minor, the submaxillary gland, the carotid artery (which lies along the lower border), the occipital and internal carotid arteries, and the tenth, eleventh, and sympathetic nerves; deeply, the vertebræ, the longus colli, intertransversales, and the small straight muscle. The terminal part of the muscle lies in contact with its fellow above the pharynx and between the guttural pouches.

Blood-supply.—Carotid, vertebral, and occipital arteries.

Nerve-supply.—Ventral branches of the cervical nerves.

8. =Rectus capitis anterior minor= (M. rectus capitis ventralis).—This is a small muscle which lies under cover of the preceding one.

Origin.—The ventral arch of the atlas.

Insertion.—The basilar process, close to the preceding muscle.

Action.—To flex the occipito-atlantal articulation.

Structure.—Fleshy.

Relations.—Below, to the preceding muscle; above, to the atlas, occipito-atlantal articulation, and the basilar process; externally, to the rectus capitis lateralis and the guttural pouch.

Blood-supply.—Occipital artery.

Nerve-supply.—Ventral branch of the first cervical nerve.

9. =Rectus capitis lateralis.=—This is a still smaller, entirely fleshy muscle, which lies for the most part under the small oblique muscle.

Origin.—The atlas, external to the preceding muscle.

Insertion.—The paramastoid or styloid process of the occipital bone.

Action.—The same as the preceding muscle.

Structure.—Fleshy.

Relations.—Superficially, the small oblique muscle, the occipital vessels, and the ventral branch of the first cervical nerve.

Blood-supply.—Occipital artery.

Nerve-supply.—Ventral branch of the first cervical nerve.

10. =Longus colli.=—This muscle covers the ventral surface of the vertebræ, from the sixth thoracic to the atlas, and is united with its fellow. It consists of two portions, thoracic and cervical.

Origin.—(1) Thoracic portion, the bodies of the first six thoracic vertebræ; (2) cervical portion, the transverse processes of the cervical vertebræ.

Insertion.—(1) Thoracic portion, the bodies and transverse processes of the last two cervical vertebræ; (2) cervical portion, the bodies of the cervical vertebræ and the tubercle on the ventral surface of the atlas.

Action.—To flex the neck.

Structure.—The muscle is composed of a succession of bundles. The largest of these constitute the thoracic part of the muscle, which has a strong tendon inserted into the last two cervical vertebræ. A bursa is interposed between the tendon and the spine at the first costo-vertebral articulation. The cervical portion consists of a number of smaller bundles, each of which passes from its origin on the transverse process of one vertebra forward and inward to its insertion into a vertebra further forward. The most anterior bundle is inserted by a strong tendon into the ventral tubercle of the atlas.

Relations.—The principal relations of the two muscles in the thorax are: ventrally, the pleura, and, further forward, the trachea and œsophagus; dorsally, the vertebræ and the costo-vertebral joints; laterally, the dorsal, superior cervical, and vertebral vessels, the sympathetic nerve, and the thoracic roots of the brachial plexus. In the neck, important relations are: ventrally, the trachea and œsophagus, the carotid artery, the vagus, sympathetic and recurrent nerves; dorsally, the vertebræ and, in the middle third of the neck, the intertransversales muscles; laterally, the scalenus, the rectus capitis anticus major, and the intertransversales (in the anterior third). The terminal part of the muscle is separated from the trachea by the œsophagus, which is here median in position.

Blood-supply.—Subcostal and vertebral arteries.

Nerve-supply.—Ventral branches of the spinal nerves.

11. =Intertransversales colli= (Mm. intertransversarii cervicis).—These are six fasciculi which occupy the spaces between the lateral aspects of the vertebræ and the transverse and articular processes. There is thus a bundle for each intervertebral articulation except the first. Each bundle consists of a dorsal and ventral portion.

Attachments.—The dorsal bundles pass from transverse process to articular process; the ventral bundles extend between adjacent transverse processes.

Action.—To bend the neck laterally.

Structure.—They contain strong tendinous intersections.

Relations.—Superficially, the mastoido-humeralis, rectus capitis anterior major, complexus, trachelo-mastoideus, splenius, scalenus, and longissimus muscles; deeply, the vertebræ, the longus colli muscle, and the vertebral vessels. The muscles are perforated by branches of these vessels and by the primary branches of the cervical nerves.

Blood-supply.—Vertebral artery.

Nerve-supply.—The cervical nerves.

LATERAL MUSCLES

This group consists of twelve pairs of muscles arranged in layers.

FIRST LAYER

1. =Trapezius cervicalis.=—Described on p. 250.

SECOND LAYER

2. =Rhomboideus cervicalis.=—Described on p. 251.

3. =Serratus magnus= (M. serratus cervicis).—Described with the thoracic part on p. 254.

THIRD LAYER

4. =Splenius.=—This is an extensive, flat, triangular muscle, partly covered by the preceding three muscles.

Origin.—The second, third, and fourth thoracic spines by means of the dorso-scapular ligament, and the funicular portion of the ligamentum nuchæ.

Insertion.—The occipital crest, the mastoid process, the wing of the atlas, and the transverse processes of the third, fourth, and fifth cervical vertebræ.

Action.—Acting together, to elevate the head and neck; acting singly, to incline the head and neck to the side of the muscle acting.

Structure.—The muscle arises in the withers from the anterior part of the dorso-scapular ligament, which also affords attachment to the rhomboideus, serratus anticus, and complexus muscles. The fibers pass upward and forward toward the head and the first cervical vertebra. The insertion on the occipital bone and the mastoid process is by means of a thin aponeurosis common to the

splenius, trachelo-mastoideus, and mastoido-humeralis. The atlantal insertion is by a strong, flat tendon, also in common with these muscles. The remaining insertions are fleshy digitations.

Relations.—Superficially, the skin and fascia, the trapezius rhomboideus, cervicalis, serratus magnus, and posterior auricular muscles; deeply, the complexus, trachelo-mastoideus, and longissimus muscles.

Blood-supply.—Deep cervical and dorsal arteries.

Nerve-supply.—Dorsal branches of the last six cervical nerves.

FOURTH LAYER

5. =Trachelo-mastoideus= (M. longissimus capitis et atlantis).—This muscle consists of two parallel, fusiform portions. It lies between the deep face of the splenius and the ventral part of the complexus.

Origin.—(1) The transverse processes of the first two thoracic vertebræ; (2) the articular processes of the cervical vertebræ.

Insertion.—(1) The mastoid process; (2) the wing of the atlas.

[Illustration:

FIG. 178.—SUPERFICIAL MUSCLES OF HORSE.

The panniculus, except the cervical part, has been removed. _a_, Trapezius cervicalis; _a′_, trapezius thoracalis; _c_, _c′_, mastoido-humeralis; _d_, sterno-cephalicus; _e_, deltoid; _f_, long head of triceps; _f′_, external head of triceps; _g_, anterior superficial pectoral; _h_, posterior deep pectoral; _h′_, anterior deep pectoral; _i_, serratus thoracis; _i′_, serratus cervicis; _k_, latissimus dorsi; _l_, obliquus abdominis externus; _l′_, aponeurosis of _l_; _m_, serratus posticus; _m′_, lumbo-dorsal fascia; _o_, tensor fasciæ latæ; _o′_, fascia lata; _o″_, gluteus superficialis; _q_, _q′_, _q″_, biceps femoris; _r_, semitendinosus; _s_, sacro-coccygeus superior; _t_, sacro-coccygeus lateralis; _u_, coccygeus; _v_, cervical panniculus; _w_, splenius; _x_, rhomboideus; _y_, tendon of trachelo-mastoideus and mastoido-humeralis; _z_, suprasinatus; _X_, wing of atlas; _2_, spine of scapula; _4′_, external epicondyle of humerus; _6_, deltoid tuberosity; _8_, olecranon; _16_, external angle of ilium; _20_, patella; _21′_, external condyle of tibia. (After Ellenberger-Baum, Anat. für Künstler.)]

Action.—Acting together, to extend the head and neck; acting singly, to flex the head and neck laterally or to rotate the atlas.

Structure.—The origin from the thoracic vertebræ is by aponeurotic slips which blend with the complexus. The succeeding fleshy portion, in passing along the neck, receives fasciculi from each of the cervical vertebræ except the first two. The dorsal division of the muscle is inserted into the mastoid process by a flat tendon which fuses with that of the splenius; the ventral division is inserted into the wing of the atlas by a ribbon-like tendon in common with the splenius and mastoido-humeralis.

Relations.—Superficially, the splenius muscle and dorsal branches of the cervical nerves; deeply, the complexus, the spinalis colli, and the oblique muscles of the head. The superior cervical vessels cross the deep face of the muscle obliquely at the level of the sixth and seventh cervical vertebræ.

Blood-supply.—Vertebral and superior cervical arteries.

Nerve-supply.—Dorsal branches of the last six cervical nerves.

6. =Complexus= (M. semispinalis capitis).—This is a large triangular muscle which lies chiefly on the ligamentum nuchæ, under cover of the splenius and trachelo-mastoideus muscles.

Origin.—(1) The second, third, and fourth thoracic spines, in common with the splenius and serratus anticus; (2) the transverse processes of the first six or seven thoracic vertebræ; (3) the articular processes of the cervical vertebræ.

Insertion.—The posterior surface of the occipital bone, external to the funicular portion of the ligamentum nuchæ.

Action.—It is the chief extensor of the head and neck. Acting singly, the muscle inclines the head to the same side.

Structure.—The origin of the muscle at the withers is aponeurotic. In the neck the bundles arising from the articular processes run obliquely upward and forward, giving the lower part of the muscle a distinct pennate character. The upper part of the belly is

crossed obliquely by four or five tendinous intersections. The insertion is by a strong tendon.

Relations.—Superficially, the rhomboideus, serratus magnus, splenius, and trachelo-mastoideus muscles; deeply, the ligamentum nuchæ, the multifidus cervicis, longissimus, and the oblique and posterior straight muscles of the head, the deep or superior cervical vessels, and the dorsal cutaneous branches of the cervical nerves.

Blood-supply.—Deep cervical, vertebral, and occipital arteries.

Nerve-supply.—Dorsal branches of the last six cervical nerves.

7. =Multifidus cervicis= (M. semispinalis colli; transverse spinous muscle of neck).—This muscle lies on the arches of the last five cervical vertebræ. It consists of five or six segments.

Origin.—The articular processes of the last five (or four) cervical and the first thoracic vertebræ.

Insertion.—The spinous processes of the cervical vertebræ.

[Illustration:

FIG. 179.—DEEPER MUSCLES OF HORSE.

_f_, Long head of triceps; _f′_, external head of triceps; _g_, anterior superficial pectoral; _h_, posterior deep pectoral; _h′_, anterior deep pectoral; _i_, serratus thoracis; _i′_, serratus cervicis; _l_, obliquus abdominis externus, and _l′_, its aponeurosis, the posterior part of which has been removed; _m_, serratus posticus; _p_, gluteus medius; _r_, semitendinosus; _s_, sacro-coccygeus superior; _t_, sacro-coccygeus lateralis; _u_, coccygeus; _v′_, biceps brachii; _x_, rhomboideus; _y_, _y′_, trachelo-mastoideus; _z_, supraspinatus; _z′_, infraspinatus; _1_, cartilage of scapula; _2_, spine of scapula; _5_, external tuberosity of humerus; _6_, deltoid tuberosity; _8_, olecranon; _16_, external angle of ilium; _19_, trochanter major; _20_, patella; _21′_, external condyle of tibia; _26_, articular processes of cervical vertebræ; _27_, parotido-auricularis; _28_, vastus externus; _28′_, rectus femoris; _28″_, trochanter tertius; _29_, semimembranosus; _30_, gastrocnemius; _31_, sacro-sciatic ligament; _32_, omo-hyoideus; _33_, complexus; _34_, rectus capitis anterior major; _35_, spinalis dorsi; _36_, longissimus dorsi; _37_, transversalis costarum; _38_, teres minor; _39_, brachialis; _40_, external intercostal; _41_, obliquus abdominis internus; _42_, iliacus; _43_, transversus abdominis. (After Ellenberger-Baum, Anat. für Künstler.)]

Action.—Acting together, to extend the neck; acting singly, to flex and rotate the neck to the opposite side.

Structure.—The muscle is composed of two sets of bundles. The superficial bundles are directed obliquely forward and inward, each passing from an articular process to the spine of the preceding vertebra. The deep bundles are shorter and run straight from an articular process to that of the preceding vertebra.

Relations.—Superficially, the complexus, longissimus, trachelo-mastoideus, and great oblique muscles; deeply, the spinalis muscle, the ligamentum nuchæ, and the arches of the vertebræ.

Blood-supply.—Deep cervical and vertebral arteries.

Nerve-supply.—Dorsal branches of the last six cervical nerves.

8. =Spinalis.=—Described with the longissimus on p. 237.

9. =Obliquus capitis posterior= (s. caudalis) (great oblique muscle of the head).—This is a strong, quadrilateral muscle, which covers the dorso-lateral aspect of the atlas and axis.

Origin.—The side of the spine and the posterior articular process of the axis.

Insertion.—The dorsal surface of the wing of the atlas.

Action.—Chiefly to rotate the atlas, and with it the head, to the same side; also to assist in extending and fixing the atlanto-axial joint.

Structure.—The muscle is composed almost entirely of parallel fleshy fibers directed obliquely forward and outward.

Relations.—Superficially, the skin, the splenius, complexus, trachelo-mastoideus, and mastoido-humeralis muscles; deeply, the arch and spine of the axis, the wing of the atlas, the atlanto-axial joint, the multifidus cervicis, the posterior straight muscles, the occipital and vertebral vessels, and the first and second cervical nerves. The terminal part of the vertebral artery joins the posterior branch of the occipital artery under cover of the muscle.

Blood-supply.—Occipital and vertebral arteries.

Nerve-supply.—Dorsal branch of the second cervical nerve.

10. =Obliquus capitis anterior= (s. cranialis) (small oblique muscle of the head).—A short, thick, quadrilateral muscle which lies on the side of the occipito-atlantal articulation.

Origin.—The anterior edge of the wing of the atlas and the fossa atlantis.

Insertion.—The styloid process and crest of the occipital bone, and the mastoid process.

Action.—Acting together, to extend the head on the atlas; acting singly, to flex the head laterally.

Structure.—The muscle contains a good deal of tendinous tissue. The direction of its fibers is forward, upward, and inward.

Relations.—Superficially, the posterior auricular muscles, artery, and nerve, the aponeurosis of the splenius, trachelo-mastoideus and mastoido-humeralis, and the parotid gland; deeply, the straight muscles, the complexus, the occipito-hyoideus, the occipito-atlantal articulation, branches of the occipital artery, and a branch of the occipital nerve.

Blood-supply.—Occipital artery.

Nerve-supply.—Dorsal branch of the first cervical nerve.

11. =Rectus capitis posterior major= (s. dorsalis major) (great posterior straight muscle of the head).—This muscle extends from the axis to the occipital bone, in contact with the ligamentum nuchæ.

Origin.—The edge of the spinous process of the axis.

Insertion.—The occipital bone, below and external to the complexus and ligamentum nuchæ.

Action.—To extend the head.

[Illustration:

FIG. 180.—DEEPEST LAYER OF MUSCLES OF NECK OF HORSE.

_a_, Obliquus capitis anterior; _b_, obliquus capitis posterior; _c_, rectus capitis lateralis; _d_, rectus capitis anterior minor; _e_, rectus capitis anterior major; _f_, longus colli; _g_, _g′_, scalenus; _h_, transversalis costarum; _i_, longissimus dorsi; _k_, spinalis et semispinalis; _l_, multifidus dorsi; _m_, multifidus cervicis; _n_, intertransversales; _o_, _o′_, rectus capitis posterior major; _p_, rectus capitis posterior minor; _q_, tendon of insertion of complexus; _1_, lamellar part, _1′_, funicular part of ligamentum nuchæ; _2_, occipital crest; _3_, paramastoid process; _4_, edge of wing of atlas; _5_, transverse, and _6_, articular, processes of cervical vertebræ; _7_, nerves of brachial plexus (cut); _8_, first rib. (Ellenberger-Baum, Anat. d. Haustiere.)]

Structure.—The muscle is fleshy and may be divided into two parallel portions, superficial and deep. The former blends somewhat with the terminal part of the complexus. The deep portion may be termed the rectus capitis posterior medius.

Relations.—Superficially, the anterior oblique, splenius, and complexus; internally, the ligamentum nuchæ; deeply, the atlas, the occipito-atlantal articulation, and the rectus capitis posterior minor. The dorsal branch of the first cervical nerve appears between this muscle and the small oblique.

Blood-supply.—Occipital artery.

Nerve-supply.—Dorsal branch of the first cervical nerve.

12. =Rectus capitis posterior minor= (s. dorsalis minor) (small posterior straight muscle of the head).—This small muscle lies under cover of the preceding.

Origin.—The dorsal surface of the atlas.

Insertion.—The occipital bone beneath the preceding muscle.

Action.—To assist the preceding muscle.

Structure.—It is fleshy and varies a good deal in volume, being sometimes small and difficult to recognize.[44] On the other hand, it is sometimes double.

Relations.—Superficially, the preceding muscle and the small oblique; deeply, the atlas and the occipito-atlantal articulation.

Blood-supply.—Occipital artery.

Nerve-supply.—Dorsal branch of the first cervical nerve.

THE FASCIÆ AND MUSCLES OF THE BACK AND LOINS

The =superficial fascia= presents no special features. The =lumbo-dorsal fascia= (Fascia lumbo-dorsalis) closely invests the muscles, but is easily stripped off the longissimus. It is attached medially to the supraspinous ligament and the spinous processes of the vertebræ; laterally, it divides into two layers. The superficial layer is practically the aponeurosis of the latissimus dorsi. The deep layer gives origin to the serratus anticus and posticus, the lumbar part of the obliquus externus abdominis, the transversus abdominis, and the retractor costæ. Its lateral edge curves under the longissimus and is attached to the ribs and lumbar transverse processes. Posteriorly, it is continuous with the gluteal fascia. At the withers it forms an important structure, the =dorso-scapular ligament=. This is a strong tendinous sheet, attached to the third, fourth, and fifth thoracic spines. Its upper part is very thick and gives origin by its superficial surface to the rhomboideus dorsi, by its anterior part to the splenius. The lower part is thin and elastic, and furnishes numerous lamellæ which intersect the scapular part of the serratus and are attached with it to the scapula. Three lamellæ are detached from the deep face of the ligament. The deepest of these passes between the longissimus and spinalis and is attached to the transverse processes of the first seven thoracic vertebræ; it gives attachment to the complexus. The middle one dips in between the longissimus and transversalis costarum. The superficial one gives origin to the serratus anticus. A strong fascial layer, the ilio-lumbar ligament, extends from the last rib to the external angle of the ilium.

There are nine pairs of muscles in this region, arranged in four layers.

FIRST LAYER

1. =Trapezius thoracalis.=

2. =Latissimus dorsi.=

SECOND LAYER

3. =Rhomboideus thoracalis.=

The foregoing are described with the other muscles which attach the thoracic limb to the trunk (p. 251).

4. =Serratus anticus= (M. serratus dorsalis inspiratorius).—This is a thin quadrilateral muscle, named from its toothed ventral border. It lies beneath the rhomboideus, serratus magnus, and latissimus dorsi.

Origin.—The lumbo-dorsal fascia and dorso-scapular ligament.

Insertion.—The external surfaces of the fifth to the eleventh or twelfth ribs inclusive.

Action.—To draw the ribs on which it is inserted forward and outward, thus assisting in inspiration.

Structure.—The muscle arises by means of a thin aponeurosis which blends with the lumbo-dorsal fascia and the aponeurosis of the latissimus dorsi. The muscle-fibers pass downward and backward to be attached to the ribs by seven or eight digitations below the outer edge of the transversalis costarum.

Relations.—Superficially, the rhomboideus, serratus magnus, latissimus dorsi, and serratus posticus; deeply, the longissimus dorsi, transversalis costarum, external intercostal muscles, and the ribs.

Blood-supply.—Intercostal arteries.

Nerve-supply.—Thoracic nerves.

5. =Serratus posticus= (M. serratus dorsalis exspiratorius).—This muscle resembles the preceding one, which it partly covers.

Origin.—The lumbo-dorsal fascia.

Insertion.—The outer surfaces of the last seven or eight ribs.

Action.—To draw the ribs backward, thus assisting in expiration.

Structure.—Similar to the preceding muscle. The fibers are directed downward and forward and terminate in seven or eight digitations, one or two of which cover the posterior teeth of the anticus. The aponeurosis blends with that of the latissimus dorsi.

Relations.—Superficially, the latissimus dorsi and external oblique; deeply, the longissimus dorsi, transversalis costarum, external intercostals, serratus anticus, and the ribs.

Blood-supply.—Intercostal and lumbar arteries.

Nerve-supply.—Thoracic nerves.

THIRD LAYER

6. =Transversalis costarum= (M. ilio-costalis).—This long, segmental muscle extends, as its name indicates, across the series of ribs, in contact with the outer edge of the longissimus dorsi.

Origin.—(1) The transverse processes of the second and third lumbar vertebræ and the deep layer of the lumbo-dorsal fascia. (2) The anterior borders and external surface of the last fifteen ribs.[45]

Insertion.—The posterior borders of the ribs and the transverse processes of the last two or three cervical vertebræ.

Action.—Chiefly to depress and retract the ribs and so help in expiration. Acting together, they may assist in extending this spine, acting singly in inclining it laterally.

Structure.—This muscle presents a distinct segmental arrangement. It is composed of a series of bundles, the fibers of which are directed forward and a little downward and outward. From these are detached two sets of tendons. The superficial tendons spring from the outer edge of the muscle. They are flat and are about half an inch in width. Each crosses two or three intercostal spaces, to be inserted on the posterior border of a rib. The deep tendons are detached from the dorsal part of the deep face of the muscle. Each passes backward across one or two intercostal spaces to its origin on the anterior border or outer surface of a rib. Small bursæ may be found between the ribs and tendons.

Relations.—Superficially, the dorsal serrati and the complexus; deeply, the external intercostals and the ribs. The lumbar origin is covered by the longissimus. The superior (deep) cervical and dorsal vessels cross the surface of the muscle at the first and second intercostal spaces respectively, and branches of the intercostal vessels and nerves emerge between the transversalis and longissimus; here a fascial layer dips in between the two.

Blood-supply.—Intercostal arteries.

Nerve-supply.—Dorsal branches of the thoracic nerves.

7. =Longissimus.=[46]—This is the largest and longest muscle in the body. It extends from the sacrum and ilium to the neck, filling up the space between the spinous processes medially and the lumbar transverse processes and the upper ends of the ribs below; consequently it has the form of a three-sided prism.

Origin.—(1) The internal angle, crest, and adjacent part of the ventral surface of the ilium; (2) the first three sacral spines; (3) the lumbar and thoracic spines and the supraspinous ligament.

Insertion.—(1) The lumbar transverse and articular processes; (2) the thoracic transverse processes; (3) the spinous and transverse processes of the last four cervical vertebræ; (4) the outer surfaces of the ribs, except the first.

Action.—Acting with its fellow, it is the most powerful extensor of the back and loins; by its cervical attachment it assists in extending the neck. By its costal attachment it may also assist in expiration. Acting singly, it flexes the spine laterally.

[Illustration:

FIG. 181.—RIGHT PORTION OF CROSS-SECTION OF BACK OF HORSE. SECTION IS CUT THROUGH SEVENTH THORACIC VERTEBRA.

_a_, Ligamentum nuchæ; _b_, trapezius muscle; _c_, cartilage of scapula; _d_, latissimus dorsi; _e_, panniculus carnosus; _f_, rhomboideus dorsi; _g_, serratus magnus; _h_, serratus anticus; _h′_, lumbo-dorsal fascia, which divides below into three layers; _i_, transversalis costarum; _k_, levator costæ; _k′_, internal intercostal muscle; _l_, longissimus dorsi; _m_, _m′_, seventh thoracic vertebra; _n_, head of eighth thoracic vertebra; _o_, head of eighth rib; _p_, seventh rib; _r_, intercostal artery and nerve; _s_, skin. The fasciæ are indicated by dotted lines. (After Ellenberger, in Leisering's Atlas.)]

Structure.—This is quite complex. The posterior part of the muscle is greatly developed and constitutes the common mass of the loins. This is covered by a strong aponeurosis which blends with the supraspinous and sacro-iliac ligaments, and is attached to the crest and inner (sacral) angle of the ilium and the first and second sacral spines; it furnishes origin to the lumbar portion of the middle gluteus. In its course further forward the muscle receives fasciculi from the lumbar and thoracic spines, but diminishes somewhat in volume. At the withers it divides into two parts. The dorsal division (spinalis et semispinalis), reinforced by bundles from the first four thoracic spines, passes forward under the complexus to be inserted into the spines of the last four cervical vertebræ. The ventral division passes forward and downward underneath the serratus magnus to be inserted into the ribs and the transverse processes of the last four cervical vertebræ. Three sets of fasciculi may be distinguished, viz.: (1) spinal, which are superficial and internal; (2) transverse, attached to the transverse and articular processes, which are internal and deep; (3) costal, which are external.

Relations.—Superficially, the middle gluteus, the lumbo-dorsal fascia, the latissimus dorsi, dorsal serrati, serratus magnus, and complexus; deeply, the multifidus, intertransversales, external intercostals, levatores costarum, the ligamentum nuchæ, and its fellow of the opposite side (in the neck).

Blood-supply.—Dorsal, superior cervical, intercostal, and lumbar arteries.

Nerve-supply.—Dorsal branches of the thoracic and lumbar nerves.

8. =Multifidus dorsi= (semispinalis of the back and loins).—This is a long segmental muscle which covers the sides of the spinous processes of the vertebræ from the sacrum to the neck.

Origin.—(1) The lateral portion of the sacrum; (2) the articular processes of the lumbar vertebræ; (3) the transverse processes of the thoracic vertebræ.

Insertion.—The spinous processes of the first two sacral, the lumbar, thoracic, and last cervical vertebræ.

Action.—Acting with its fellow, it is an extensor of the spine; acting singly, it flexes it laterally.

Structure.—It is composed of a series of bundles which are directed obliquely forward and upward. Each fasciculus passes over several vertebræ to its insertion. In the posterior part of the series the bundles cross two or three vertebræ and are inserted into the summits of the spines. Anteriorly, the bundles have a more horizontal direction, cross three to five vertebræ, and are inserted into the sides of the spines considerably below their summits. A further complication consists in the fusion of several bundles into a common insertion.

Relations.—Superficially, the longissimus; deeply, the vertebral spines.

Blood-supply.—Intercostal and lumbar arteries.

Nerve-supply.—Dorsal branches of the thoracic and lumbar nerves.

9. =Intertransversales lumborum.=—These are very thin muscular and tendinous strata, which occupy the spaces between the transverse processes of the lumbar vertebræ except the fifth and sixth.

Action.—To assist in flexing the loins laterally.

Relations.—Superficially, the longissimus; deeply, the quadratus lumborum.

Blood-supply.—Lumbar arteries.

Nerve-supply.—Lumbar nerves.

THE FASCIA AND MUSCLES OF THE TAIL

The muscles of the tail are inclosed in the strong =coccygeal fascia=, which is continuous in front with the gluteal fascia and blends with the lateral sacro-iliac ligament. At the root of the tail it is loosely attached to the subjacent muscles, but further back it is intimately adherent to them. From its deep face are detached septa which pass between the muscles to become attached to the vertebræ.

1. =Coccygeus= (Compressor coccygis; ischio-coccygeus).—This is a flat, triangular muscle which lies chiefly between the sacro-sciatic ligament and the rectum.

Origin.—The pelvic surface of the sacro-sciatic ligament near the ischiatic spine.

Insertion.—The first four coccygeal vertebræ and the coccygeal fascia.

Action.—Acting together, to depress (flex) the tail, compressing it over the perineum; acting singly, to depress and incline it to the same side.

Structure.—The origin of the muscle is aponeurotic. Becoming fleshy, its fibers pass upward and backward and divide into two layers. The outer layer is attached to the vertebræ, the inner to the fascia; included between the two lie the intertransversales. When the tail is raised, the ventral edges of the muscles produce a distinct ridge at either side of the anus.

Relations.—Outwardly, the sacro-sciatic ligament and the semimembranosus; inwardly, the rectum and the sacro-coccygeus ventralis muscle. The internal pudic artery crosses the outer face of the origin of the muscle.

2. =Sacro-coccygeus superior= (M. sacro-coccygeus dorsalis medialis; erector s. extensor coccygis).—This muscle lies along the dorso-median aspect of the tail, in contact with its fellow.

Origin.—The last three sacral spines and some of the coccygeal spines.

Insertion.—The dorsal surface of the coccygeal vertebræ.

Action.—Acting together, to elevate (extend) the tail; acting singly, to elevate and incline it laterally.

Structure.—The muscle has a strong rounded belly. It is inserted by means of short tendons which fuse with those of the next muscle.

Relations.—Superficially, the coccygeal fascia; internally, its fellow; laterally, the sacro-coccygeus lateralis; deeply, the vertebræ.

3. =Sacro-coccygeus lateralis= (M. sacro-coccygeus dorsalis lateralis; curvator coccygis).—This muscle lies immediately lateral to the preceding.

[Illustration:

FIG. 182.—CROSS-SECTION OF TAIL OF HORSE CLOSE TO ANUS.

_34_, Coccygeal vertebra; _35_, sacro-coccygeus superior; _36_, intertransversalis; _37_, sacro-coccygeus inferior; _38_, coccygeus; _39_, recto-coccygeus; _40_, coccygeal fascia. (After Ellenberger-Baum, Anat. für Künstler.)]

[Illustration:

FIG. 183.—MUSCLES OF PERINEUM OF HORSE.

_a_, Coccygeus; _b_, retractor ani; _c_, _c′_, sphincter and externus; _d_, recto-coccygeus; _e_, sacro-coccygeus inferior lateralis; _f_, retractor penis; _g_, bulbo-cavernosus; _h_, ischio-cavernosus; _i_, internal pudic artery; _k_, anus; _l_, penis. (After Ellenberger-Baum, Top. Anat. d. Pferdes.)]

Origin.—The sides of the sacral spines, with the multifidus, and the transverse processes of the sacral and coccygeal vertebræ.

Insertion.—The lateral surface of the coccygeal vertebræ, except the first four.

Action.—Acting with its fellow, to assist the preceding muscle in elevating the tail; acting singly, to incline it to the same side.

Structure.—This muscle appears to be a direct continuation of the multifidus dorsi. The belly is fusiform and receives reinforcing fasciculi from the transverse processes of the sacrum. This is succeeded by bundles of tendons, as many as four lying alongside of each other.

Relations.—Superficially, the lateral sacro-iliac ligament and the coccygeal fascia; dorsally, the sacro-coccygeus superior; ventrally, the intertransversales; deeply, the vertebræ and a branch of the lateral coccygeal artery and accompanying vein and nerve.

4. =Intertransversales caudæ= (Mm. intertransversarii caudæ).—These consist of muscular bundles which lie on the lateral aspect of the tail, between the preceding muscle and the sacro-coccygeus inferior. They begin on the lateral edge of the sacrum and occupy the spaces between the transverse processes, to which they are attached. They are, however, not arranged in a strict segmental manner.

Action.—Acting together, to fix the coccygeal vertebræ; acting singly, to assist in lateral flexion.

5. =Sacro-coccygeus inferior= (Mm. sacro-coccygei ventrales; depressor coccygis).—This muscle lies on the ventral aspect of the sacrum and coccyx. It is composed of two portions, described by Bourgelat and the German anatomists as separate muscles.

(_a_) The =outer portion= (M. coccygeus ventralis lateralis) is much the larger of the two. It arises from the outer part of the ventral surface of the sacrum, about as far forward as the third foramen, and is inserted into the transverse processes and ventral surface of the coccygeal vertebræ.

(_b_) The =inner portion= (M. sacro-coccygeus ventralis medialis) arises from the ventral surface of the sacrum internal to the preceding muscle and the first eight coccygeal vertebræ, and is inserted into the ventral surfaces of the coccygeal vertebræ.

Action.—Acting together, to depress (flex) the tail; acting singly, to incline it laterally also.

Structure.—The outer portion has a somewhat compressed belly, and receives bundles from the transverse processes of the coccygeal vertebræ. The inner portion is much smaller and shorter, reaching only about to the middle of the tail.

Relations.—Ventrally, the pelvic and coccygeal fasciæ; dorsally, the sacrum, coccygeal vertebræ, and the intertransversales; laterally, the sacro-sciatic ligament, the coccygeus, and the coccygeal fascia; medially, its fellow, the recto-coccygeus, and the middle coccygeal vessels. Branches of the lateral coccygeal vessels and nerves lie between the outer division of the muscle and the intertransversales.

Blood-supply.—Middle and lateral coccygeal arteries.

Nerve-supply.—Coccygeal nerves.

THE MUSCLES OF THE THORAX

These consist of seven muscles or sets of muscles, which are attached to the thoracic vertebræ, to the ribs and their cartilages, and to the sternum. Functionally, they are muscles of respiration.

1. =Levatores costarum.=—These constitute a series of small muscles which occupy and overlie the upper ends of the intercostal spaces.

Origin.—The transverse processes of the thoracic vertebræ.

Insertion.—The external surfaces of the upper ends of the ribs posterior to the vertebral origin.

Action.—To draw the ribs forward in inspiration.

Structure.—Arising by tendinous fibers, each muscle passes backward and outward and expands at its insertion. Some fibers pass over one rib and are inserted on a succeeding one. At the first and last spaces the muscle cannot be distinguished from the

external intercostal, of which it is in reality only a specially developed part.

Relations.—Superficially, the longissimus dorsi; deeply, the ribs, internal intercostal muscles, and the intercostal vessels and nerves.

Blood-supply.—Intercostal arteries.

Nerve-supply.—Intercostal nerves.

2. =External intercostals= (Mm. intercostales externi).—Each of these occupies an intercostal space, from the levatores to the sternal extremity of the rib. They do not occupy the intercartilaginous spaces.

Origin.—The posterior borders of the ribs.

Insertion.—The anterior borders and external surfaces of the succeeding ribs.

Action.—To draw the ribs forward in inspiration.

Structure.—The fibers are directed downward and backward. There is a considerable admixture of tendinous tissue. The thickness of the muscles gradually diminishes toward the lower ends of the spaces.

[Illustration:

FIG. 184.—DORSAL AND LUMBAR REGIONS OF HORSE, DORSAL VIEW. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

Relations.—Superficially, the serratus magnus, latissimus dorsi, serratus anticus and posticus, longissimus dorsi, transversalis costarum, rectus thoracis, deep pectorals, obliquus abdominis externus, and panniculus; deeply, the internal intercostals and (in the upper part of the spaces) the intercostal vessels and nerves.

Blood-supply.—Intercostal and internal thoracic arteries.

Nerve-supply.—Intercostal nerves.

3. =Internal intercostals= (Mm. intercostales interni).—These occupy the entire length of the intercostal spaces, including their interchondral portion.

Origin.—The anterior borders of the ribs and their cartilages.

Insertion.—The posterior borders of the preceding ribs and cartilages.

Action.—To draw the ribs backward in expiration. It seems probable, however, that the intercartilaginous portion is inspiratory.[47]

Structure.—The direction of the fibers is oblique downward and forward. There is a smaller amount of tendinous tissue than in the external set, and the thickness diminishes from below upward. In the upper part of the spaces fibers sometimes cross a rib in a fashion similar to the subcostals of man. A thin aponeurosis separates the internal from the external intercostal muscle in each space.

Relations.—Superficially, the levatores costarum and the external intercostals; deeply, the endothoracic fascia and pleura, the transversus thoracis, diaphragm, transversus abdominis, and the internal thoracic and asternal vessels. In the upper part of the intercostal spaces the intercostal vessels and nerves lie between the internal and external intercostal muscle, but below they lie chiefly on the deep face of the inner muscle.

Blood-supply.—Intercostal and internal thoracic arteries.

Nerve-supply.—Intercostal nerves.

4. =Retractor costæ.=—This is a small triangular muscle which lies behind the last rib, chiefly under cover of the serratus posticus.

Origin.—The transverse processes of the first three or four lumbar vertebræ by means of the lumbar fascia.

Insertion.—The posterior border of the last rib.

Action.—To retract the last rib.

Structure.—The muscle arises by a thin aponeurosis. Its fibers are parallel to those of the adjacent internal oblique.

Relations.—Superficially, the serratus posticus and external oblique; deeply, the transversus abdominis.

Blood-supply.—Lumbar arteries.

Nerve-supply.—Lumbar nerves.

5. =Rectus thoracis= (M. transversus costarum; lateralis sterni).—This is a thin muscle which lies under cover of the deep pectoral muscles. It is directed obliquely backward and downward, and crosses the lower part of the first three intercostal spaces.

Origin.—The outer surface of the first rib, below the scalenus.

Insertion.—The cartilage of the third or fourth rib. The aponeurosis usually joins the rectus abdominis. It may reach the sternum.

Action.—It may assist in inspiration or concur with the rectus abdominis.

Relations.—Superficially, the deep pectoral muscles; deeply, the intercostal muscles and the ribs.

6. =Transversus thoracis= (Triangularis sterni).—This is a flat muscle situated on the thoracic surface of the sternum and the cartilages of the sternal ribs.

Origin.—The sternal ligament.

Insertion.—The cartilages of the ribs, from the second to the eighth inclusive.

Action.—It draws the costal cartilages inward and backward, thus assisting in expiration.

Structure.—Each muscle has the form of a scalene triangle, of which the base is the strongly serrated external border. The muscle contains a good deal of tendinous tissue. The anterior bundles are directed forward and outward; the posterior backward and outward.

Relations.—Superiorly, the endothoracic fascia and pleura; inferiorly, the costal cartilages, the internal intercostal muscles, and the internal thoracic vessels.

Blood-supply.—Internal thoracic artery.

Nerve-supply.—The intercostal nerves.

7. =Diaphragm.=—This is a broad, unpaired muscle which forms a partition between the thoracic and abdominal cavities.[48] In outline it has some resemblance to a palm-leaf fan. In form it is dome-shaped, compressed laterally. On a median section it is seen to have a general direction downward and forward from the lumbar vertebræ to the xiphoid cartilage. The thoracic surface is strongly convex, and is covered by the pleura. The abdominal surface is deeply concave, and is covered for the most part by the peritoneum. The muscle consists of a peripheral fleshy portion, two muscular crura, and a tendinous center.

Attachments.—(1) =Costal part=: The cartilages of the ninth to the fifteenth ribs, and the last three ribs at an increasing distance from their sternal ends.

(2) =Sternal part=: The upper surface of the xiphoid cartilage.

(3) =Lumbar part=: (_a_) The =right crus= is attached to the inferior common ligament, and by this means to the first four or five lumbar vertebræ. (_b_) The =left crus= is attached in a similar fashion to the first and second lumbar vertebræ.

Action.—It is the principal muscle of inspiration and increases the longitudinal diameter of the chest. The contraction produces a general lessening of the curvature of the diaphragm. In the expiratory phase the costal part and crura lie directly on the body walls, so that the bases of the lungs are in contact with the tendinous center and sternal portion only. In ordinary inspiration the fleshy rim recedes from the chest-wall, so that the bases of the lungs move backward to a line about parallel with the curve formed by the cartilages of the asternal ribs, and about four or five inches (ca. 10 to 12 cm.) therefrom. It is stated that the inspiratory movement affects the tendinous center much less than the fleshy part, since the posterior vena cava is firmly attached to the former. It should

be noted, however, that the direction of the thoracic part of the vena cava in the expiratory phase is oblique upward and backward. Thus it would seem that there is no anatomical reason why the diaphragm should not move as a whole in ordinary inspiration at least.

Structure.—The =costal part= (Pars costalis) consists of a series of digitations which meet, or are separated by a very narrow interval from, the transversus abdominis; between the two are the asternal vessels. From the tenth rib backward the attachments are to the ribs at an increasing distance above the costo-chondral junctions. Thus at the last rib the attachment is four to five inches (10 to 12 cm.) from the lower end. Anteriorly, the origin extends along the ninth costal cartilage to the xiphoid cartilage. From these points of origin the fibers curve inward and forward to join the tendinous center. The =right crus= (Crus dextrum) is about twice as thick as the left one and is also longer. It arises by a strong tendon from the lumbar vertebræ (by means of the inferior common ligament). The tendon is succeeded by a rounded belly which leaves the vertebral column, at the last thoracic vertebra. Passing downward and forward, its fibers spread out and join the tendinous center. The =left crus= (Crus sinistrum) arises by a thin tendon from the inferior common ligament at the first and second lumbar vertebræ. This is succeeded by a triangular belly which joins the central tendon. Between the crura and the attachment to the last rib the edge of the muscle crosses the ventral surface of the psoas muscles without attachment, forming the so-called lumbo-costal arch; here the thoracic and abdominal cavities are separated only by the serous membranes and some areolar tissue. The =tendinous center= (Centrum tendineum) resembles the periphery in outline, but is more elongated. It is partially divided into right and left halves by the descent of the crura into it. It is composed largely of radiating fibers, but many interlace in various directions; this is specially evident around the foramen venæ cavæ, which is encircled by fibers. A strong tendinous layer extends across below the hiatus œsophageus.

[Illustration:

FIG. 185.—DIAPHRAGM OF HORSE, ABDOMINAL SURFACE.

_1_, Inferior common ligament; _2_, _2′_, tendons of crura; _3_, lumbar sympathetic trunks; _4_, external spermatic nerve; _5_, _5′_, great splanchnic nerves; _6_, cisterna chyli (opened); _7_, _7′_, œsophageal continuations of vagus nerves; _8_, lymph gland; _9_, coronary ligament of liver (cut); _10_, right lateral ligament of liver (cut); _11_, left lateral ligament of liver (cut); _12_, falciform ligament of liver (cut); _A.l._, lumbo-costal arch; _N.i._, intercostal nerve; _C.d._, right crus; _C.s._, left crus; _A_, aorta; _Ca_, cœliac artery; _Oe._, œsophagus; _V.c._, posterior vena cava; _V.p._, phrenic veins. (After Schmaltz, Atlas d. Anat. d. Pferdes.)]

The diaphragm is pierced by three foramina. (1) The =hiatus aorticus= is an interval between the two crura and below the last thoracic vertebra. It contains the posterior aorta, vena azygos, and cisterna chyli. (2) The =hiatus œsophageus= (or foramen sinistrum) perforates the right crus near its junction with the tendinous center. It is situated a little to the left of the median plane and two or three inches below the thirteenth thoracic vertebra (in expiration). It transmits the œsophagus, the vagus nerves, and the œsophageal branch of the gastric artery. (3) The =foramen venæ cavæ= (s. dextrum) pierces the tendinous center about an inch to the right of the median plane, and about six inches below the twelfth thoracic vertebra (in expiration). The vena cava is firmly attached to the margin of the opening.[49]

Relations.—The thoracic surface is related to the endothoracic fascia, pleuræ, pericardium, the bases of the lungs, and the ribs in part. The abdominal surface is in great part covered by the peritoneum, and is related chiefly to the liver, stomach, spleen, pancreas, kidneys and adrenals, and the anterior flexures of the colon. The sympathetic and splanchnic nerves pass between the crus and the psoas muscles on each side. The asternal vessels perforate the edge of the muscle at the ninth costo-chondral joint.

Blood-supply.—Phrenic and asternal arteries.

Nerve-supply.—Phrenic nerves (from the fifth, sixth, and seventh cervical nerves).

THE ABDOMINAL MUSCLES

The =superficial fascia= covering the lateral and ventral walls of the abdomen is continuous dorsally with the lumbo-dorsal fascia, in front with the thoracic fascia, and behind with the gluteal fascia. In the inguinal region it forms part of the fascia of the penis or of the mammary glands. At the lower part of the flank it forms a fold which is continuous with the fascia of the thigh near the stifle joint. In this fold are the precrural lymph glands. Medially it blends with the linea alba. It contains the abdominal portion of the panniculus carnosus.

The =abdominal panniculus= (M. cutaneus maximus) covers a large part of the lateral surface of the abdomen and thorax. The general direction of its fibers is longitudinal. Its posterior extremity forms the basis of the fold of the flank. Its anterior extremity is inserted by a thin tendon into the internal tuberosity of the humerus, with the posterior deep pectoral muscle. Its dorsal edge may be indicated by a line drawn from the upper end of the thirteenth rib to the fold of the flank. Its ventral limit corresponds to a line drawn from the fold to a point about a handbreadth external to the umbilicus, and from here to a point a little above the level of the elbow. Behind the shoulder the fibers become oblique and blend with the scapular portion. The aponeurosis extends ventrally to the linea alba, dorsally to the supraspinous ligament. The muscle is intimately adherent to the skin, so that special care is necessary in removing the latter. Its deep face, on the other hand, is loosely attached to the underlying structures by a quantity of areolar tissue which is more or less loaded with fat (panniculus adiposus) in animals in good condition. The large external thoracic (“spur”) vein is partially embedded in the lower part of the muscle. Its action is to twitch the skin.

The =deep fascia= is represented chiefly by the =abdominal= tunic (Tunica flava abdominis). This is a sheet of elastic tissue which assists the muscles in supporting the great weight of the abdominal viscera. It is practically coextensive with the obliquus externus, which it covers. Ventrally it is thick, and is intimately adherent to the aponeurosis of the muscle. Laterally it becomes thinner and is more easily separated, although fibers from it dip in between the muscle-bundles. It is continued for some distance upon the intercostals and serratus magnus. Traced forward, it passes as a thin layer beneath the posterior deep pectoral muscle. Posteriorly it is attached to the external angle of the ilium. In the inguinal region it forms the deep fascia of the prepuce or of the mammary glands.

The =linea alba= is a median fibrous raphé which extends from the xiphoid cartilage to the symphysis pubis. It is formed chiefly by the junction of the aponeuroses of the oblique and transverse muscles, but partly by longitudinal fibers. A little behind its middle is a cicatrix which indicates the position of the umbilical opening of the fœtus.

1. =Obliquus abdominis externus= (great oblique; external oblique of the abdomen).—This is the most extensive of the abdominal muscles. It is a broad sheet, irregularly triangular in shape, widest behind. Its fibers are directed chiefly downward and backward.

Origin.—(1) The outer surfaces of the last fourteen ribs, and the fascia over the external intercostal muscles; (2) the lumbo-dorsal fascia.

Insertion.—(1) The linea alba and the prepubic tendon; (2) the external angle and shaft of the ilium; (3) the internal femoral fascia.

Action.—(1) To compress the abdominal viscera, as in defecation, micturition, parturition, and expiration; (2) to flex the trunk (arch the back); (3) acting singly, to flex the trunk laterally.

Structure.—The muscle is composed of a fleshy portion and an aponeurosis. The =muscular portion= lies on the lateral wall of the thorax and abdomen. It arises by a series of digitations, the anterior four of which alternate with those of the serratus magnus. The origin may be indicated by a slightly curved line (concave above) drawn from the lower part of the fifth rib to the external angle of the ilium. The fibers are directed downward and backward and terminate on the aponeurosis, except in the flank, where they are almost horizontal in direction. The line of junction is a curve (concave above) extending from the upper edge of the posterior deep pectoral muscle toward the external angle of the ilium. The =aponeurosis= is intimately attached to the abdominal tunic, and its fibers are largely interwoven ventrally with those of the aponeurosis of the internal oblique. By this fusion is formed the outer sheath of the rectus abdominis, which blends at the linea alba with that of the opposite side. In the inguinal region the aponeurosis divides into two chief layers; one of these curves upward and backward and is inserted into the external angle of the ilium and the prepubic tendon. Between these points the aponeurosis is much strengthened and is called the =inguinal= (Poupart’s) =ligament= (Ligamentum inguinale). This curves upward and somewhat forward, becomes thin, and blends with the iliac fascia. It forms the posterior wall of the inguinal canal. About an inch (ca. 2 to 3 cm.) in front of the pubis and about two inches (ca. 4 to 5 cm.) from the median plane the aponeurosis is pierced by a slit-like opening,[50] the =external inguinal ring= (Annulus inguinalis subcutaneus). This is the external orifice of the inguinal canal. Its long axis is directed outward and forward, and is about four inches (ca. 10 cm.) in length. The inner angle is rounded and is well defined by the junction of the inguinal ligament with the prepubic tendon, but the outer angle is not so sharply defined. The borders or pillars are constituted by arciform fibers of the aponeurosis of the external oblique (Crus mediale, laterale). The =femoral layer= of the aponeurosis (Lamina femoralis) passes on to the inner surface of the thigh, where it blends with the femoral fascia. A thin =iliac layer= (Lamina iliaca) passes over the outer margin of the iliacus to the external border of the ilium.

Relations.—Superficially, the skin, the panniculus carnosus, the abdominal tunic, and the posterior deep pectoral muscle; deeply, the ribs and their cartilages, the intercostal muscles, the internal oblique, the contents of the inguinal canal, and the sartorius and gracilis.

Blood-supply.—Intercostal and lumbar arteries.

Nerve-supply.—Intercostal and lumbar nerves.

2. =Obliquus abdominis internus= (small oblique; internal oblique of the abdomen).—This muscle is situated under the preceding one. Its fibers are directed downward, forward, and inward. It forms a triangular curved sheet with the base behind.

[Illustration:

FIG. 186.—VENTRAL MUSCLES OF HORSE, AFTER REMOVAL OF GREATER PART OF PANNICULUS CARNOSUS AND ABDOMINAL TUNIC. SARTORIUS AND GRACILIS REMOVED FROM RIGHT THIGH.

_c_, Mastoido-humeralis; _g_, anterior superficial pectoral; _g′_, posterior superficial pectoral; _h_, posterior deep pectoral; _l′_, aponeurosis of obliquus abdominis externus; _t_, pectineus; _u_, ilio-psoas; _v_, semimembranosus; _w_, gracilis; _x_, sartorius; _y_, vastus internus; _z_, _z′_, adductor; _14_, sternum; _14′_, cariniform cartilage. (After Ellenberger-Baum, Anat. f. Künstler.)]

Origin.—The external angle of the ilium and the adjacent part of the inguinal (Poupart's) ligament.

Insertion.—(1) The cartilages of the last four or five ribs; (2) the linea alba and the prepubic tendon.

Action.—Similar to that of the preceding muscle.

Structure.—Like the external oblique, it is composed of a fleshy portion and an aponeurosis. The fleshy portion is fan-shaped, and is situated chiefly in the flank. At its iliac origin it is covered by a glistening aponeurosis. Traced inward and downward along the abdominal surface of the inguinal ligament, the muscular origin is found to become much thinner, and also becomes loosely attached to the ligament. About four or five inches (ca. 10 to 12 cm.) from the linea alba the muscle separates from the ligament and forms the anterior wall of the inguinal canal. The abdominal orifice of the canal, the =internal inguinal ring=[51] (Annulus inguinalis abdominalis), is found here. It is normally a narrow slit, bounded in front by the edge of the internal oblique, and behind by the inguinal ligament. The =aponeurosis= is to a great extent blended with that of the external oblique, being, indeed, considerably interwoven with it ventrally. Where it covers the rectus abdominis it is attached to the tendinous inscriptions of that muscle.

Relations.—Superficially, the external oblique; deeply, the rectus abdominis, transversus abdominis, and the peritoneum.

Blood-supply.—Circumflex iliac, lumbar, and intercostal arteries.

Nerve-supply.—Ventral branches of the lumbar nerves.

3. =Rectus Abdominis.=—This muscle is confined to the ventral part of the abdominal wall; it extends from the lower part of the chest-wall to the pubis.

Origin.—The cartilages of the fifth to the ninth ribs inclusive, and the adjacent surface of the sternum.

Insertion.—The pubis, by means of the prepubic tendon.

Action.—Similar to that of the oblique muscles. It is specially adapted to flex the lumbo-sacral joints and the lumbar and thoracic parts of the spine.

Structure.—The fibers of the muscle are directed longitudinally. Nine to eleven transverse bands of fibrous tissue extend in an irregular manner across the muscle. These are termed =inscriptiones tendineæ=. They strengthen the muscle and serve to prevent separation of its fibers. The width of the muscle is greatest about its middle.

Relations.—Superficially, the aponeuroses of the oblique muscles (which constitute the external rectus sheath), and the posterior deep pectoral; deeply, the transversus, intercostals, the cartilages of the ribs, and the sternum. The posterior abdominal artery runs along the outer edge of the muscle posteriorly, and the anterior abdominal artery on or in its anterior part.

Blood-supply.—Anterior and posterior abdominal arteries.

Nerve-supply.—Intercostal and lumbar nerves.

4. =Transversus abdominis.=—This muscle, named from the general direction of its fibers, is a triangular curved sheet. Its lateral part is muscular, its ventral aponeurotic.

Origin.—(1) The inner surfaces of the distal ends or the cartilages of the asternal ribs, meeting the costal attachment of the diaphragm; (2) the transverse processes of the lumbar vertebræ, by means of the deep layer of the lumbo-dorsal fascia.

Insertion.—The xiphoid cartilage and the linea alba.

Action.—Similar to that of the oblique muscles.

Structure.—The =muscular part= is a sheet of parallel bundles of fibers, directed downward and inward. It is thickest over the cartilages of the ribs, and from here it thins out greatly toward the aponeurosis and the lumbar region. The fibers of the =aponeurosis= directly continue those of the fleshy part. Posteriorly it becomes extremely thin and blends with the aponeuroses of the oblique muscles. It covers the deep face of the rectus, so forming the internal rectus sheath.

Relations.—Superficially, the oblique and straight muscles, the retractor costæ, the cartilages of the asternal ribs, and the internal intercostal muscles; deeply, the transversalis fascia and the peritoneum. The =transversalis fascia= is little developed in the horse, and is very thin in emaciated subjects, but in animals in good condition it contains a good deal of fat. It blends with the iliac fascia and descends into the inguinal canal. The asternal artery runs along the interval between the origin of the transversus and the costal part of the diaphragm. The intercostal nerves pass down over the external surface of the muscle, to which they give branches. Branches of the first three lumbar nerves are similarly disposed further back.

Blood-supply.—Intercostal, lumbar, and asternal arteries.

Nerve-supply.—Intercostal and lumbar nerves.

5. =Cremaster externus.=—This small muscle may be regarded as a detached portion of the internal oblique, with which it blends at its origin (Figs. 272, 450).

Origin.—The iliac fascia, near the origin of the sartorius.

Insertion.—The tunica vaginalis communis.

Action.—To raise the tunica vaginalis, and with it the testicle.

Structure.—The muscle arises by a thin aponeurosis which is succeeded by a flat muscular belly about one and a half to two inches (ca. 4 to 5 cm.) in width.[52] It passes down the inguinal canal on the postero-external surface of the tunica vaginalis, to which it is rather loosely attached. On reaching the point where the tunic is reflected on to the tail of the epididymis, the muscle is firmly attached to the outer surface of the tunic by short tendinous fibers.

Relations.—The muscle lies between the peritoneum and the fascia transversalis in front and the iliac fascia and inguinal ligament behind. On reaching the internal ring it descends the inguinal canal on the postero-external surface of the tunica vaginalis communis.

Blood-supply.—External spermatic or cremasteric artery.

Nerve-supply.—External spermatic nerve.

=The Inguinal Canal.=—This term (Canalis inguinalis) is applied to an oblique passage through the posterior part of the abdominal wall.[53] It begins at the internal inguinal or abdominal ring, and extends obliquely downward, inward, and somewhat forward, to end at the external inguinal or subcutaneous ring. Its anterior wall is formed by the fleshy posterior part of the internal oblique muscle, and the posterior wall by the strong tendinous inguinal (Poupart's) ligament. The average length of the canal, measured along the spermatic cord, is about four inches (ca. 10 cm.). The =internal inguinal ring= (Annulus inguinalis abdominalis) is bounded in front by the thin margin of the internal oblique muscle, and behind by the inguinal ligament. It is directed approximately from the edge of the prepubic tendon toward the external angle of the ilium. Its length is about four or five inches (ca. 10 to 12 cm.). The edge of the muscle is attached to the surface of the ligament here by delicate connective tissue, except where structures

intervene between the walls of the canal. Consequently the limits of the ring are not very clearly defined. The =external inguinal ring= (Annulus inguinalis subcutaneus) is a well defined slit in the aponeurosis of the external oblique muscle, situated lateral to the prepubic tendon. Its long axis is directed from the edge of the prepubic tendon outward and forward, and its average length is about four inches (ca. 10 cm.). The canal contains in the male the spermatic cord, the tunica vaginalis, the external cremaster muscle, the external pudic artery and a small satellite vein, and the inguinal lymph vessels and nerves. In the female it contains the mammary vessels and nerves; in the bitch it also lodges the round ligament of the uterus, inclosed in a tubular process of peritoneum.

The two rings do not correspond in direction, so that the length of the canal varies greatly when measured at different points. The inner angle of the internal ring lies almost immediately above that of the external ring, but the outer angle is situated five to six inches (ca. 12 to 15 cm.) from that of the external ring. The inner angles of the external rings are well defined and distinctly palpable in the living subject; they are about three to four inches (ca. 8 to 10 cm.) apart.

=The Prepubic Tendon.=—The =prepubic tendon= is essentially the tendon of insertion of the two recti abdominis, but also furnishes attachment to the obliqui, the graciles, and the pectinei. It is attached to the anterior borders of the pubic bones, including the ilio-pectineal eminences. It has the form of a very strong thick band, with concave lateral borders which form the inner boundaries of the external inguinal rings. Its direction is oblique upward and backward.[54] Its structure is somewhat complex. Most of the fibers of the posterior part extend from one ilio-pectineal eminence to the other. The fibers which belong to the recti curve in to the median line. The aponeuroses of the internal oblique muscles are inserted into its abdominal surface, and the inguinal ligaments are attached to and continue across it in arciform fashion. The anterior part of the tendon of origin of the gracilis is fused with it ventrally, and many of the fibers of the pectineus arise from it. It gives off on either side a strong round band, the so-called =pubo-femoral= or =accessory ligament=, which is inserted into the fossa of the head of the femur with the round ligament (_vide_ hip joint).

MUSCLES OF THE THORACIC LIMB

I. THE MUSCLES OF THE SHOULDER GIRDLE (Figs. 177, 178, 179, 186)

This group consists of those muscles which connect the thoracic limb with the head, neck, and trunk. The group naturally falls into two divisions—dorsal and ventral.[55]

A. DORSAL DIVISION

This division consists of two layers which overlie the proper muscles of the neck and back.

FIRST LAYER

1. =Trapezius.=—This is a flat, triangular muscle, the base of the triangle corresponding with the spine. It is divided by an aponeurotic portion into two divisions:

(=a=) =Trapezius cervicalis.=—_Origin._—The funicular portion of the ligamentum nuchæ, from the second cervical to the third thoracic vertebra.

Insertion.—The spine of the scapula and the fascia of the shoulder and arm.

(=b=) =Trapezius thoracalis s. dorsalis.=—_Origin._—The supraspinous ligament, from the third to the tenth thoracic vertebra.

Insertion.—The tubercle of the spine of the scapula.

Action.—Acting as a whole, to elevate the shoulder; the cervical portion draws the scapula forward and upward and the thoracic portion draws it backward and upward.

Structure.—The muscle arises by a short, thin aponeurosis, from which the fibers of the flat fleshy portion converge to the spine of the scapula and the aponeurosis which separates the two portions. The cervical fascia joins the ventral edge of the cervical portion to the mastoido-humeralis, or the two muscles may unite here.

Relations.—Superficially, the skin and fascia; deeply, the rhomboideus, latissimus dorsi, supraspinatus, infraspinatus, deltoid, splenius, serratus magnus, and anterior deep pectoral muscles, and the cartilage of the scapula.

Blood-supply.—Deep cervical and intercostal arteries.

Nerve-supply.—Spinal accessory nerve.

SECOND LAYER

This consists of two muscles—the rhomboideus and the latissimus dorsi.

2. =Rhomboideus.=—This consists of two portions:

(=a=) =Rhomboideus cervicalis s. cervicis.=—_Origin._—The funicular portion of the ligamentum nuchæ, from the second cervical to the second thoracic vertebra.

Insertion.—The internal surface of the cartilage of the scapula.

(=b=) =Rhomboideus thoracalis s. dorsalis.=—_Origin._—The spinous processes of the second to the seventh thoracic vertebra by means of the dorso-scapular ligament.

Insertion.—The inner surface of the cartilage of the scapula.

Action.—To draw the scapula upward and forward. When the limb is fixed the cervical portion will elevate the neck.

Structure.—The cervical portion is narrow, pointed at its anterior extremity, and lies along the funicular part of the ligamentum nuchæ, to which it is attached by short tendon bundles. The fibers are directed for the most part longitudinally. The thoracic portion is quadrilateral in shape, and its fibers are nearly vertical. Its deep face is intimately attached to the dorso-scapular ligament.

Relations.—Superficially, the skin and fascia (over a small area), the trapezius, and the cartilage of the scapula; deeply, the dorso-scapular ligament, the splenius, complexus, longissimus dorsi, and serratus anticus.

Blood-supply.—Dorsal and superior cervical arteries.

Nerve-supply.—Sixth cervical nerve.

3. =Latissimus Dorsi.=—This is a wide muscle which has the form of a right-angled triangle. It lies for the most part under the skin and panniculus, on the lateral wall of the thorax, from the spine to the arm.

Origin.—The lumbo-dorsal fascia—and by this means from the lumbar and thoracic spines as far forward as the highest point of the withers.

Insertion.—The internal tubercle of the humerus, in common with the teres major.

Action.—To draw the humerus upward and backward and flex the shoulder joint. If the limb is advanced and fixed, it draws the trunk forward.

Structure.—The muscle arises by a wide aponeurosis, which fuses with that of the serratus posticus and with the lumbo-dorsal fascia. The muscular portion is at first rather thin, but by the convergence of its fibers becomes thicker as it approaches the arm. The anterior fibers pass almost vertically downward over the dorsal angle of the scapula and its cartilage. The posterior fibers are directed downward and forward. The thick belly formed by the convergence of these passes under the triceps to end on the flat tendon of insertion, which is common to this muscle and the teres major.

Blood-supply.—Subscapular, intercostal, and lumbar arteries.

Nerve-supply.—Brachial plexus (eighth cervical and dorsal roots).

B. VENTRAL DIVISION

1. =Mastoido-humeralis= (M. brachiocephalicus; levator humeri).—This muscle extends along the side of the neck from the head to the arm. It is incompletely divisible into two portions.

Origin.—(1) The mastoid process of the petrous temporal bone and the occipital crest; (2) the wing of the atlas and the transverse processes of the second, third, and fourth cervical vertebræ.

Insertion.—The deltoid tuberosity and the curved rough line which extends from this to the distal extremity of the humerus.

Action.—When the head and neck are fixed, to draw the limb forward, extending the shoulder joint. When the limb is fixed, to extend the head and neck, if the muscles act together; acting separately, to incline the head and neck to the same side.

Structure.—As already mentioned, the muscle is capable of incomplete division into two parts, the line of division being indicated by the emergence of superficial branches of the ventral divisions of the cervical nerves. The mastoid portion (M. cleido-mastoideus) partly overlaps the other portion (M. cleido-transversarius), which lies dorsal to it. The former is attached to the mastoid process and the occipital bone by a broad tendon which fuses with that of the splenius and trachelo-mastoideus; it is also attached to the tendon of insertion of the sterno-cephalicus by aponeurosis. The dorsal portion is attached to the transverse processes by four fleshy digitations. The belly of the muscle is adherent superficially to the cervical fascia and the panniculus, and deeply to the subscapulo-hyoideus. In front of the shoulder its deep face is marked by a tendinous intersection of variable development.[56] Here the muscle becomes wider, covers the shoulder joint, passes between the brachialis and biceps, and is inserted by means of a wide tendon which it shares with the superficial pectoral muscle.

Relations.—Superficially, the skin, cervical fascia, the parotid gland, the panniculus, brachialis, and branches of the cervical nerves; deeply, the splenius, trachelo-mastoideus, rectus capitis anterior major, omo-hyoideus, serratus magnus, anterior deep pectoral and biceps muscles, the inferior cervical artery, the prescapular lymph glands, and branches of the cervical nerves. The ventral edge of the muscle forms the dorsal boundary of the jugular furrow. The dorsal border may be in contact with the cervical trapezius, or separated from it by a variable interval.

Blood-supply.—Inferior cervical, carotid, and vertebral arteries.

Nerve-supply.—Spinal accessory and cervical nerves.

The =pectoral fascia= is a thin membrane covering the surface of the pectoral muscles, to which it is, for the most part, pretty intimately attached. It detaches a layer which passes between the superficial and deep pectorals. At the posterior edge of the triceps another layer is given off, which passes on the outer surface of this muscle to blend with the scapular fascia; the deeper layer becomes continuous with the subscapular and cervical fasciæ.

The =pectoral muscles= form a large fleshy mass which occupies the space between the ventral part of the chest-wall and the shoulder and arm. They are clearly divisible into a superficial and a deep layer. The superficial layer may be subdivided into two portions by careful dissection; the deep layer is clearly made up of two muscles.

2. =Superficial pectoral= (M. pectoralis superficialis).

(=a=) =Anterior superficial pectoral= (portio clavicularis s. descendens; pectoralis anticus).—This is a short, thick, somewhat rounded muscle, which extends between the anterior part of the sternum and the front of the arm. It forms a distinct prominence on the front of the breast, which is easily recognized in the living animal.

Origin.—The cariniform cartilage of the sternum.

Insertion.—(1) The curved line of the humerus with the mastoido-humeralis; (2) the fascia of the arm.

Action.—To adduct and advance the limb.

Structure.—The belly of the muscle is convex on its superficial face, but deeply it is flattened where it overlaps the posterior superficial pectoral. Here the two muscles are usually pretty intimately attached to each other, and care must be exercised in making the separation. The tendon of insertion blends with that of the mastoido-humeralis and with the fascia of the arm. At the middle line of the breast a furrow occurs between the two muscles; laterally, another furrow, containing the cephalic vein, lies between the muscle and the mastoido-humeralis.

Relations.—Superficially, the skin, fascia, and panniculus; deeply, the posterior division, the deep pectoral, and the biceps. The cephalic vein lies in the groove between this muscle and the mastoido-humeralis.

(=b=) =Posterior superficial pectoral= (portio sternocostalis; pectoralis transversus).—This is a wide muscular sheet which extends from the ventral edge of the sternum to the fascia on the inner surface of the forearm.

Origin.—(1) The ventral edge of the sternum as far back as the sixth cartilage; (2) a fibrous raphé common to the two muscles.

Insertion.—(1) The fascia on the proximal third of the forearm; (2) the curved line of the humerus with the preceding muscle.

Action.—To adduct the limb and to tense the fascia of the forearm.

Structure.—It is thin and pale, and mixed with a good deal of fibrous tissue. The right and left muscles fuse at a median fibrous raphé. The tendon of insertion unites with the fascia on the inner side of the forearm for the most part; only a small part in front, about an inch in width, is attached to the humerus.

Relations.—Superficially, the skin, fascia, and the preceding muscle; deeply, the deep pectoral, the biceps, and the brachialis; at the elbow, the posterior radial vessels, the median nerve, and the inner and middle flexors of the carpus.

3. =Deep pectoral= (M. pectoralis profundus).—This muscle is much thicker and more extensive in the horse than the superficial pectoral. It consists of two distinct portions.

(=a=) =Anterior deep pectoral= (portio prescapularis; pectoralis parvus).—This division is prismatic and extends from the anterior part of the lateral surface of the sternum to the cervical angle of the scapula.

Origin.—The anterior half of the lateral surface of the sternum and the cartilages of the first four ribs.

Insertion.—The aponeurosis which covers the supraspinatus at its dorsal end, and the scapular fascia.

Action.—To adduct and retract the limb; when the limb is advanced and fixed, to draw the trunk forward.

Structure.—The muscle is almost entirely fleshy. It describes a curve (convex anteriorly), passing at first forward, then upward over the front of the shoulder, a little to its inner side, and finally upward and backward along the anterior border of the supraspinatus. It is loosely attached to the latter muscle, and terminates in a pointed end which becomes more firmly attached near the cervical angle of the scapula.

Relations.—Superficially, the skin and fascia, the panniculus, superficial pectoral, trapezius, and mastoido-humeralis muscles, the cephalic vein, and the inferior cervical artery; deeply, the posterior deep pectoral, biceps, supraspinatus, omo-hyoideus, and serratus magnus muscles, the brachial vessels, and the branches of the brachial plexus of nerves.

(=b=) =Posterior deep pectoral= (portio humeralis s. ascendens; pectoralis magnus).—This is much the largest of the pectoral group in the horse. It is somewhat triangular or fan-shaped.

Origin.—(1) The abdominal tunic; (2) the xiphoid cartilage and ventral aspect of the sternum; (3) the cartilages of the fourth to the ninth ribs.

Insertion.—(1) The internal tuberosity of the humerus; (2) the external lip of the bicipital groove; (3) the tendon of origin of the coraco-brachialis.

Action.—To adduct and retract the limb; if the limb is advanced and fixed, to draw the trunk forward.

Structure.—This muscle is also almost entirely fleshy. Its posterior part is wide and thin, but as the muscle is traced forward, it becomes narrower and much thicker. It passes forward and slightly upward in a gentle curve to its insertion. The humeral insertion is just below that of the inner division of the supraspinatus. Part of the fibers are inserted by means of a tendinous band which binds down the tendon of the biceps and is attached to the external lip of the bicipital groove, and a small part is attached to the tendon of origin of the coraco-brachialis.

Relations.—Superficially, the skin, panniculus, and superficial pectoral; deeply, the abdominal tunic, the external oblique, the rectus abdominis et thoracis, the brachial vessels, and branches of the brachial plexus of nerves. The external thoracic vein lies along the outer or upper border.

Blood-supply.—Internal and external thoracic, inferior cervical, anterior circumflex, and intercostal arteries.

Nerve-supply.—Pectoral (or thoracic) nerves, from the brachial plexus.

4. =Serratus magnus= (M. serratus ventralis).—This is a large, fan-shaped muscle, situated on the lateral surface of the neck and thorax. It derives its name from the serrated ventral edge of its thoracic portion. It consists of a cervical and a thoracic portion.

(=a=) =Cervical part= (M. serratus cervicis; levator scapulæ hominis).

Origin.—The transverse processes of the last four or five cervical vertebræ.

Insertion.—The anterior triangular area on the costal surface of the scapula and the adjacent part of the cartilage.

(=b=) =Thoracic part= (M. serratus thoracis; serratus anterior hominis).

Origin.—The external surfaces of the first eight or nine ribs.

Insertion.—The posterior triangular area on the costal surface of the scapula and the adjacent part of the cartilage.

Action.—The two muscles form a sort of sling in which the trunk is suspended. Contracting together, they raise the thorax; contracting singly, the weight is shifted to the limb on the side of the muscle acting. The two parts can contract separately and are antagonistic in their action on the scapula. The cervical part draws the base of the scapula toward the neck, while the thoracic part has the opposite action; these effects concur in the backward and forward swing of the limb respectively. With the limb fixed, the cervical part extends (raises) the neck or inclines it laterally. The thoracic part may act as a muscle of forced inspiration.

Structure.—In the domesticated animals there is no such clear division of the muscle as is found in man and the apes. On account of the difference in action, however, it seems desirable to distinguish the two portions. The cervical part is thick and almost entirely fleshy. The thoracic part has on its superficial face a thick, tendinous layer which may sustain the weight of the trunk when the muscle substance relaxes. The ventral edge presents distinct digitations, the last four of which alternate with those of the obliquus externus abdominis, and are covered by the abdominal tunic. The fourth, fifth, and sixth digitations extend nearly to the distal ends of the ribs. The last digitation is small and may be absent. Exceptionally additional digitations may be attached to the tenth or eleventh rib or to the fascia over the intercostal muscles. The fibers converge to the insertion, which is thick and is intersected by elastic lamellæ derived from the dorso-scapular ligament.

Relations.—Superficially, the mastoido-humeralis, trapezius, deep pectoral, subscapularis, teres major, latissimus dorsi, panniculus carnosus, the abdominal tunic, the brachial vessels, and the long thoracic nerve; deeply, the splenius, complexus, longissimus, transversalis costarum, the ribs and external intercostal muscles, and branches of the superior cervical and dorsal arteries.

Blood-supply.—Superior cervical, dorsal, vertebral, and intercostal arteries.

Nerve-supply.—Brachial plexus.

II. THE MUSCLES OF THE SHOULDER

Under this head will be described those muscles which arise on the scapula and end on the arm; they may be divided into two groups—one covering the dorsum, the other the venter of the scapula.

The =superficial fascia= of the shoulder and arm contains the panniculus carnosus of this region, and may be considered to be continued on the inner side of the limb by the subscapular fascia.

The =thoracic= or =scapulo-humeral portion= of the =panniculus= (M. cutaneus scapulæ et humeri) arises by a thin aponeurosis from the ligamentum nuchæ at the withers. The fleshy portion begins over the upper part of the scapula and extends to the elbow. Its fibers have in general a dorso-ventral direction. It is continuous behind with the abdominal portion.

The =deep fascia= of the shoulder and arm (Fascia omobrachialis) is much more developed and important. It is strong and tendinous, and is intimately adherent to the muscles on the outer surface of the scapula, between which it detaches =intermuscular septa=, which are attached to the spine and borders of the scapula. The brachial portion is, for the most part, only loosely attached to the underlying muscles, for which it forms sheaths; it is attached to the humerus, especially to the lips of the bicipital groove and the deltoid tuberosity. It blends distally with the tendon of insertion of the biceps, and is continued by the antibrachial fascia.

A. EXTERNAL GROUP (Figs. 178, 179)

1. =Deltoid= (M. deltoideus; long abductor of the arm; scapular portion of the deltoid of man).—This lies partly on the triceps in the angle between the scapula and humerus, partly on the infraspinatus and teres minor.

Origin.—(1) The upper part of the posterior border of the scapula; (2) the spine of the scapula, by means of the strong aponeurosis which covers the infraspinatus.

Insertion.—The deltoid tuberosity of the humerus.

Action.—To flex the shoulder joint and abduct the arm.

Structure.—The origin of the muscle is partly aponeurotic, partly fleshy. The aponeurosis fuses with that of the infraspinatus; the posterior part is attached to the scapula immediately in front of the origin of the long head of the triceps. The belly of the muscle lies for the most part in a cavity formed in the triceps. It is widest about its middle.

Relations.—Superficially, the skin, fascia, panniculus, and mastoido-humeralis; deeply, the infraspinatus, teres minor, triceps, and brachialis muscles, and branches of the posterior circumflex artery and axillary nerve.

Blood-supply.—Subscapular artery (chiefly through the posterior circumflex).

Nerve-supply.—Suprascapular and axillary nerves.

2. =Supraspinatus.=—This muscle occupies the supraspinous fossa, which it fills, and beyond which it extends, thus coming in contact with the subscapularis.

Origin.—The supraspinous fossa, the spine, and the lower part of the cartilage of the scapula.

Insertion.—The inner and outer lips of the bicipital groove.

Action.—To extend the shoulder joint. It also assists in preventing dislocation.

Structure.—The surface of the muscle is covered by a strong aponeurosis, from the deep face of which many fibers arise. The muscle is thin at its origin from the cartilage, but becomes considerably thicker below. At the neck of the scapula it divides into two branches, between which the tendon of origin of the biceps emerges. These branches, fleshy superficially, tendinous deeply, are inserted into the lips of the bicipital groove. They are united by a fibrous membrane already mentioned in connection with the deep pectoral muscle; some fibers are attached to this membrane and the capsule of the shoulder joint.

Relations.—Superficially, the skin, fascia, panniculus, trapezius, and mastoido-humeralis; deeply, the scapula and its cartilage, the subscapularis muscle, and the suprascapular vessels and nerve; in front, the anterior deep pectoral muscle; behind, the spine of the scapula and infraspinatus muscle.

Blood-supply.—Suprascapular and posterior circumflex arteries.

Nerve-supply.—Suprascapular nerve.

3. =Infraspinatus.=—This muscle occupies the greater part of the infraspinous fossa.

Origin.—The infraspinous fossa and the scapular cartilage.

Insertion.—(1) The outer tuberosity of the humerus, distal to the outer insertion of the supraspinatus; (2) the posterior eminence of the outer tuberosity.

Action.—To abduct the arm and rotate it outward.[57] It also plays the part of a lateral ligament.

Structure.—This muscle is also covered by a strong aponeurosis, from which many fibers arise, and by means of which the deltoid is attached to the spine of the scapula. A thick tendinous layer partially divides the muscle into two strata, and, coming to the surface at the shoulder joint, constitutes the chief means of insertion. This tendon, an inch or more (3 cm.) in width, passes over the posterior eminence of the external tuberosity of the humerus; it is bound down by a fibrous sheet, and a =synovial bursa= is interposed between the tendon and the bone. When the long insertion is cut and reflected, the short insertion, partly tendinous, partly fleshy, is exposed.

Relations.—Superficially, the skin, fascia, panniculus, trapezius, and deltoid; deeply, the scapula and its cartilage, the shoulder joint and capsule, the long head of the triceps, the teres minor, and the nutrient artery of the scapula.

Blood-supply.—Subscapular artery.

Nerve-supply.—Suprascapular and axillary nerves.

4. =Teres minor.=—This is a much smaller muscle than the foregoing. It lies chiefly on the triceps, under cover of the deltoid and infraspinatus.

Origin.—(1) The rough lines on the distal and posterior part of the infraspinous fossa; (2) a small part of the posterior border of the scapula, about its middle; (3) a tubercle near the rim of the glenoid artery.

Insertion.—The deltoid tuberosity and a small area just above it.

Action.—To flex the shoulder joint and to abduct the arm; also to assist in outward rotation.

Structure.—The muscle is not rounded in the horse and ox, but flat and triangular. Its origin from the posterior border of the scapula is by means of an aponeurosis which also gives origin to fibers of the infraspinatus and triceps. A =bursa= is commonly found between the terminal part of the muscle and the capsule of the shoulder joint, and is often continuous with that of the infraspinatus.

Relations.—Superficially, the deltoid and infraspinatus muscles; deeply, the scapula, the shoulder joint, and the triceps muscle.

Blood-supply.—Subscapular artery (circumflex branches).

Nerve-supply.—Axillary nerve.

B. INTERNAL GROUP

1. =Subscapularis.=—This muscle occupies the subscapular fossa, beyond which, however, it extends both before and behind.

Origin.—The subscapular fossa.

Insertion.—The posterior eminence of the internal tuberosity of the humerus.

Action.—To adduct the humerus.

[Illustration:

FIG. 187.—MUSCLES OF THORACIC LIMB OF HORSE, INTERNAL VIEW.

_3_, _4_, Rhomboideus; _5_, latissimus dorsi; _8_, posterior deep pectoral; _9_, anterior deep pectoral; _11_, supraspinatus; _15_, subscapularis; _16_, teres major; _20_, long head of triceps; _22a_, _22b_, tensor fasciæ antibrachii; _23_, internal head of triceps. (After Ellenberger, in Leisering's Atlas.)]

Structure.—The muscle is flat and triangular, with the base upward. The latter is thin and interdigitates with the scapular attachments of the serratus. Below this the belly thickens and becomes narrower. It is covered by an aponeurosis, and contains a considerable amount of tendinous tissue. The tendon of insertion is crossed by the tendon of origin of the coraco-brachialis; it is intimately adherent to the capsule of the shoulder joint, and may be regarded as replacing the internal ligament of the latter. A small bursa may occur here.

Relations.—Superficially, the scapula and shoulder joint, the supraspinatus, triceps, and teres major muscles; deeply, the serratus magnus muscle, the brachial vessels, and the chief branches of the brachial plexus. The subscapular vessels run along or near the posterior edge of the muscle.

Blood-supply.—Subscapular artery.

Nerve-supply.—Subscapular nerves (from the brachial plexus).

2. =Teres major= (Teres internus; adductor of the arm).—This muscle is flat, widest about its middle, and lies chiefly on the deep face of the triceps.

Origin.—The dorsal angle and the adjacent part of the posterior border of the scapula.

Insertion.—The tubercle on the inner surface of the shaft of the humerus, in common with the latissimus dorsi.

Action.—To flex the shoulder joint and adduct the arm.

Structure.—It is for the most part fleshy, but the origin consists of an aponeurosis which blends with that of the tensor fasciæ antibrachii. The insertion is by a flat tendon which fuses with that of the latissimus dorsi.

Relations.—Superficially, the triceps, infraspinatus, and deltoid muscles; deeply, the serratus magnus muscle. The subscapular vessels lie in a groove between the anterior edge of this muscle and the posterior border of the subscapularis; near the shoulder joint the posterior circumflex artery and the axillary nerve emerge between the two muscles. The deep face of the muscle is crossed by the thoracic branches of the brachial plexus, and by the branch of the subscapular artery which supplies the latissimus dorsi.

Blood-supply.—Subscapular artery.

Nerve-supply.—Axillary nerve.

3. =Coraco-brachialis= (Coraco-humeralis).—This muscle lies on the inner surface of the shoulder joint and the arm.

Origin.—The coracoid process of the scapula.

Insertion.—(1) A small area above the internal tubercle of the humerus; (2) the middle third of the anterior surface of the humerus.

Action.—To adduct the arm and to flex the shoulder joint.

Structure.—The long tendon of origin emerges between the subscapularis and the inner branch of the supraspinatus. It passes over the terminal part of the subscapularis and is provided with a =synovial sheath=. The muscular part spreads out and divides into two portions. The smaller and shorter portion is inserted into the proximal third of the shaft of the humerus, close to the origin of the lateral head of the triceps; the larger and longer portion is inserted into the middle third of the humerus, in front of the internal tubercle and the inner head of the triceps.

Relations.—Externally, the subscapularis muscle and the humerus; internally, the deep pectoral and brachialis muscles. The anterior circumflex artery and the nerve to the biceps usually emerge between the two insertions, and the brachial vessels lie along the posterior border of the muscle.

Blood-supply.—Anterior circumflex artery.

Nerve-supply.—Musculo-cutaneous nerve.

4. =Capsularis= (Scapulo-humeralis posticus s. gracilis).—This is a very small muscle, which lies on the back of the capsule of the shoulder joint.

Origin.—The scapula, close to the rim of the glenoid cavity.

Insertion.—The posterior surface of the shaft of the humerus, a short distance below the head.

Action.—It may perhaps tense the capsule of the shoulder joint and prevent its being pinched during flexion.

Structure.—It is fleshy and usually about the breadth of a finger. It may, however, consist of only a few bundles of fibers; sometimes it is double. Its attachment to the joint capsule is slight. It passes through the brachialis muscle to reach its insertion.

Relations.—Superficially, the teres minor and triceps muscles; deeply, the teres major and subscapularis muscles, and the capsule of the joint.

Blood-supply.—Posterior circumflex artery.

Nerve-supply.—Axillary nerve.

III. THE MUSCLES OF THE ARM

This group consists of five muscles which are grouped around the humerus. They arise from the scapula and the humerus, and are inserted into the forearm. They act on the elbow joint and the fascia of the forearm.

[Illustration:

FIG. 188.—BICEPS AND BRACHIALIS MUSCLES OF HORSE. (After Ellenberger-Baum, Anat. für Künstler.)]

1. =Biceps brachii= (Coraco-radialis; flexor brachii).—This is a strong, somewhat rounded muscle, which lies on the anterior surface of the humerus.

Origin.—The tuberosity of the scapula.

Insertion.—(1) The bicipital tuberosity of the radius; (2) the internal lateral ligament of the elbow joint; (3) the fascia of the forearm and the tendon of the extensor carpi radialis.

Action.—To flex the elbow joint, to fix the shoulder, elbow, and carpus in standing, and to tense the fascia of the forearm.

Structure.—The muscle is inclosed in a double sheath of fascia, which is attached to the lips of the bicipital groove and the deltoid ridge of the humerus. The tendon of origin is moulded on the bicipital groove; it is very strong and dense and is partly cartilaginous. Its play over the groove is facilitated by the large =bicipital bursa= (Bursa intertubercularis). The synovial membrane covers not only the deep face of the tendon, but extends somewhat over the edges to the superficial face. A well-marked tendinous intersection runs through the belly of the muscle and divides distally into two portions. Of these, the short, thick one is inserted into the bicipital tuberosity and detaches fibers to the internal lateral ligament. The long tendon (Lacertus fibrosus) is thinner, blends with the fascia of the forearm, and ends by fusing with the tendon of the extensor carpi radialis.

Relations.—Externally, the mastoido-humeralis and brachialis muscles; internally, the posterior deep pectoral and the superficial pectoral muscles; in front, the anterior deep pectoral muscle; behind, the humerus, the coraco-brachialis muscle, the anterior circumflex and anterior radial vessels, and the musculo-cutaneous nerve.

Blood-supply.—Branches of the brachial and anterior radial arteries.

Nerve-supply.—Musculo-cutaneous nerve.

2. =Brachialis= (Humeralis obliquus s. externus; brachialis anticus).—This muscle occupies the musculo-spiral groove of the humerus.

Origin.—The proximal third of the posterior surface of the humerus.

Insertion.—The inner surface of the neck of the radius (under cover of the lateral ligament) and the arciform ligament.

Action.—To flex the elbow joint.

Structure.—The peculiar spiral course of this muscle gave rise to the name often applied to it—humeralis obliquus. Beginning on the posterior surface of the shaft, close to the head of the humerus, it winds over the lateral surface, crosses the biceps very obliquely, and finally reaches the inner side of the forearm by passing between the biceps and the extensor carpi. It is entirely fleshy, with the exception of its relatively slender tendon of insertion.

Relations.—Externally the skin and fascia, the teres minor, deltoid, triceps (lateral head), biceps, and mastoido-humeralis muscles. The anterior radial artery crosses the deep face of the muscle in its distal third, and the radial nerve accompanies the muscle in the distal half of the musculo-spiral groove.

Blood-supply.—Brachial artery.

Nerve-supply.—Radial nerve.

3. =Tensor fasciæ antibrachii= (Fig. 187)[58] (Scapulo-ulnaris; long extensor of the forearm; accessory anconeus of the latissimus dorsi).—This is a thin muscle which lies on the inner surface of the triceps.

Origin.—The tendon of insertion of the latissimus dorsi and the posterior border of the scapula.

Insertion.—(1) The fascia of the forearm; (2) a small eminence on the posterior border of the olecranon.

Action.—(1) To tense the fascia of the forearm and to extend the elbow joint.

Structure.—The origin consists of a very thin aponeurosis which blends with those of the caput longum and the latissimus dorsi. The muscular portion is quite thin in its anterior part, somewhat thicker behind, and is narrower than the aponeurotic origin. It is succeeded by an aponeurotic insertion, which ends chiefly by blending with the fascia of the forearm a little below the elbow. There is, however, a small but constant tendinous attachment to the olecranon.

Relations.—Externally, the panniculus, triceps (long and internal heads), the inner and middle flexors of the carpus, and the ulnar vessels and nerve; internally, the latissimus dorsi, serratus magnus, and posterior pectoral muscles.

Blood-supply.—Subscapular, ulnar, and deep brachial arteries.

Nerve-supply.—Radial nerve.

4. =Triceps brachii= (Figs. 178, 179, 187) (Brachial triceps; triceps extensor cubiti).—This, together with the preceding muscle, constitutes the large muscular mass which fills the angle between the posterior border of the scapula and the humerus. It is clearly divisible into three heads, as described below.

(=a=) =Long head= (Caput longum tricipitis; anconeus longus; caput magnum).—This, the largest and longest of the three heads, is a powerful, thick, triangular muscle, which extends from the posterior border of the scapula to the olecranon.

Origin.—The posterior border of the scapula.

Insertion.—The outer and posterior part of the summit of the olecranon.

Action.—(1) To extend the elbow joint; (2) to flex the shoulder joint.

Structure.—The muscle arises by a wide, strong aponeurosis from the posterior border of the scapula. From this the bundles of the fleshy portion converge to the short, strong tendon of insertion. A careful examination will show that the muscle is penetrated by a tendinous intersection from which many fibers take origin obliquely. The superficial face is covered by an aponeurosis which is specially developed at its distal part. A small =bursa= occurs under the tendon of insertion.

Relations.—Externally, the panniculus, deltoid, infraspinatus, teres minor, and the external head; internally, the tensor fasciæ antibrachii, teres major, latissimus dorsi, and posterior deep pectoral muscles, and the subscapular vessels; in front, the brachialis, and the inner head, the deep brachial and posterior circumflex vessels, and the axillary and radial nerves; behind, the skin and fascia.

Blood-supply.—Subscapular and deep brachial arteries.

Nerve-supply.—Radial nerve.

(=b=) =External head= (Caput laterale tricipitis s. anconeus lateralis s. externus; caput medium).—This is a strong, quadrilateral muscle, which lies on the outer surface of the arm. Its proximal third is covered by the deltoid and teres minor muscles; the remainder only by the thin panniculus and the skin.

Origin.—The deltoid tuberosity and the curved rough line which extends from it to the neck of the humerus.

Insertion.—(1) A small prominent area on the outer surface of the olecranon; (2) the tendon of the long head.

Action.—To extend the elbow joint.

Structure.—The origin consists of short tendinous fibers. The belly is thick, and is composed of parallel bundles which are directed obliquely downward and backward. They are inserted partly into the tendon of the long head and partly into the olecranon below and in front of that tendon.

Relations.—Externally, the deltoid, teres minor, and panniculus muscles; internally, the long and inner heads and the brachialis muscle. Branches of the circumflex vessels and axillary nerve emerge between the posterior edge of the muscle and the long head. The deep face of the muscle is related to the branches of the deep brachial artery and of the radial nerve.

Blood-supply.—Posterior circumflex and deep brachial arteries.

Nerve-supply.—Radial nerve.

(=c=) =Internal head= (Fig. 193) (Caput mediale tricipitis; anconeus medialis s. internus; caput parvum).—This is much the smallest of the three heads. It is situated on the inner surface of the arm, and extends from the middle third of the humerus to the olecranon.

Origin.—The middle third of the inner surface of the shaft of the humerus, behind and below the internal tubercle.

Insertion.—The inner and fore part of the summit of the olecranon, between the insertion of the long head and the origin of the ulnar head of the flexor perforans.

Action.—To extend the elbow joint.

Structure.—The muscle is fleshy except at its insertion, where it has a flat tendon, under which a small bursa may be found.

Relations.—Externally, the humerus, brachialis, anconeus, and the external head; internally, the posterior deep pectoral, coraco-brachialis, teres major, latissimus dorsi, and tensor fasciæ antibrachii muscles, the brachial and deep brachial vessels, and the median and ulnar nerves; behind, the long head, branches of the deep brachial vessels, and the radial nerve.

Blood-supply.—Deep brachial and ulnar arteries.

Nerve-supply.—Radial nerve.

5. =Anconeus= (M. anconeus parvus s. subanconeus).—This is a small fleshy muscle which covers the olecranon fossa and is covered by the triceps. It is somewhat difficult to separate from the outer head.

Origin.—The distal third of the posterior surface of the humerus.

Insertion.—The outer surface of the olecranon.

Action.—To extend the elbow joint, and to raise the capsule of the joint and prevent its being pinched during extension.

Structure.—It is almost entirely fleshy, and is adherent by its deep face to the joint capsule.

Relations.—Superficially, the triceps muscle; deeply, the humerus and the elbow joint.

Blood-supply.—Deep brachial artery.

Nerve-supply.—Radial nerve.

IV. FASCIÆ AND MUSCLES OF THE FOREARM AND MANUS

The forearm is covered on three sides by the muscles of this group, leaving the inner surface of the radius for the most part subcutaneous. The extensors of the carpus and digit lie on the anterior (dorsal) and external part of the region, while the flexors occupy the posterior (volar) surface.

The =fascia= of the =forearm= (Fascia antibrachii) forms a very strong and complete investment for all the muscles of the region. The =superficial fascia= is thin, and disappears at the carpus by fusing with the deep fascia. The =deep fascia= is very strong and tendinous in character. It furnishes insertion at its upper and inner part to the tensor fasciæ antibrachii and posterior superficial pectoral muscles; at its upper anterior and outer part, to aponeuroses from the mastoido-humeralis and biceps. It is attached at the elbow by its deep face to the outer tuberosities of the humerus and radius, to the ulna, and to the lateral ligaments. On the inner surface of the forearm it blends with the periosteum on the subcutaneous surface of the radius. It is closely adherent to the surface of the extensor muscles, but is rather loosely attached to the flexors. From its deep face are detached =intermuscular septa=, which form sheaths for the muscles and are attached to the underlying bones. The principal septa are: (_a_) One which passes between the common extensor (in front) and the lateral extensor and flexor carpi externus (behind); (_b_) one between the common extensor and the extensor carpi radialis; (_c_) one between the inner and middle flexors of the carpus.

The =carpal fascia= (Fascia carpi) is a direct continuation of that of the forearm. It is attached chiefly to the tuberosities at the distal end of the radius, to the accessory carpal (pisiform) bone, and to the lateral ligaments. In front it forms the so-called =anterior annular ligament= (Ligamentum carpi dorsale), bridging over the grooves and binding down the extensor tendons and their synovial sheaths. Behind it is greatly thickened and forms the =posterior annular= or =transverse ligament= of the carpus (Ligamentum carpi transversum). This stretches across from the accessory carpal bone to the internal lateral ligament and the proximal extremity of the inner metacarpal bone. It thus completes the carpal canal, in which lie the flexor tendons, their synovial sheath, and the principal vessels and nerves of the region.

The =fascia= of the =metacarpus= and =digit= (Fascia metacarpea et digitalis) is, in general, thinner than the preceding. It is attached to the tendons, ligaments, and the exposed bony prominences—especially to the small metacarpal bones. On the flexion surface of the fetlock joint it is much thickened by fibers passing transversely from one sesamoid bone to the other, forming an =annular ligament= which binds down the flexor tendons in the sesamoid groove or canal. Distal to this is a second thick quadrilateral sheet (Ligamentum vaginale) which covers and is adherent to the tendon of the flexor perforatus. It is attached on either side by two bands to the borders of the first phalanx, thus firmly binding down the flexor tendons. A little further down a crescentic =fibro-elastic sheet= covers the terminal expansion of the deep flexor tendon. It is attached on either side by a strong band to the side of the first phalanx about its middle.

A. EXTENSOR DIVISION

1. =Extensor carpi radialis= (M. extensor carpi radialis s. radialis dorsalis; extensor metacarpi magnus; anterior extensor of the metacarpus).—This is the largest muscle of the extensor division, and lies on the anterior (dorsal) surface of the radius.

Origin.—(1) The external condyloid crest of the humerus; (2) the coronoid fossa.

Insertion.—The tuberosity on the anterior (dorsal) surface of the proximal extremity of the large (third) metacarpal bone.

Action.—To extend and fix the carpal joint and to flex the elbow joint.

Structure.—The belly of the muscle is rounded, and runs out to a point at the distal third of the forearm. The tendon, which runs nearly the whole length of the fleshy portion, appears on the surface of the latter about its middle; here the muscle shows a distinctly pennate arrangement. The tendon passes through the middle groove at the distal extremity of the radius and over the capsule of the carpal joint, bound down by the anterior annular ligament and invested with a =synovial sheath=. The latter begins three to four inches (ca. 8 to 10 cm.) above the carpus and extends almost to the insertion of the tendon. In the lower half of the forearm the deep fascia blends with the tendon, and here the latter is joined by the long tendon of the biceps.

Relations.—Superficially, the skin, fascia, and the oblique extensor; deeply, the capsule of the elbow joint, the biceps tendon, the radius, the carpal joint capsule, the anterior radial artery, and the radial nerve; externally, the anterior or common extensor; internally, at the elbow, the brachialis and biceps.

Blood-supply.—Anterior radial artery.

Nerve-supply.—Radial nerve.

2. =Anterior= or =common digital extensor= (M. extensor digitalis communis; anterior extensor of the phalanges; extensor pedis).—This muscle lies external to the foregoing, which it resembles in general form, although less bulky.

Origin.—(1) The front of the distal extremity of the humerus, just external to the coronoid fossa; (2) the external tuberosity on the proximal extremity of the radius, the external lateral ligament of the elbow, and the external border of the radius at the junction of its proximal and middle thirds; (3) the external surface of the shaft of the ulna; (4) the fascia of the forearm.

[Illustration:

FIG. 190.—MUSCLES OF LEFT THORACIC LIMB OF HORSE, FROM ELBOW DOWNWARD, ANTERIOR VIEW.

_a_, Extensor carpi radialis; _g′_, superficial pectoral muscle. (After Ellenberger-Baum, Anat. für Künstler.)]

Insertion.—(1) The extensor (or pyramidal) process of the third phalanx; (2) the anterior surface of the proximal extremities of the first and second phalanges.

Action.—To extend the digital and carpal joints, and to flex the elbow joint.

Structure.—The muscle is a compound one, representing the common extensor, together with vestiges of the proper extensors of the digits. Usually at least =two heads= may be distinguished. The principal or humeral head (Caput humerale) arises from the front of the extensor epicondyle of the humerus in common with the extensor carpi. Its belly is fusiform, and terminates in a point near the distal third of the radius. The tendon appears on the surface of the muscle about the middle of the belly, the arrangement being pennate. The tendon passes downward through the outer of the two large grooves on the front of the distal end of the radius, and over the capsule of the carpal joint. Passing down over the front of the metacarpus, it inclines gradually inward, reaching the middle line of the limb near the fetlock. A little below the middle of the first phalanx it is joined by the branches of the suspensory ligament, and the tendon thus becomes much wider. Two =synovial membranes= facilitate the play of the tendon. The proximal one is a =sheath= which begins about three inches (ca. 7 to 8 cm.) above the carpus, and terminates at the proximal end of the metacarpus. At the fetlock a =bursa= occurs between the tendon and the joint capsule, but otherwise the two are adherent. The smaller head, arising chiefly from the radius and ulna, is often divisible into two parts (Fig. 443). The larger of these (Caput radiale, muscle of Phillips)[59] arises from the outer tuberosity and outer border of the radius, and from the lateral ligament of the elbow joint. The flat belly is succeeded by a delicate tendon, which accompanies the principal tendon over the carpus (included in the same sheath), and then passes outward to fuse with the tendon of the lateral extensor. Usually a slip is detached which is inserted on the proximal extremity of the first phalanx, or ends in the fascia here. The smaller and deeper division (Caput ulnare, muscle of Thiernesse)[60] is usually somewhat difficult to isolate. It arises from the ulna close to the interosseous space. It has a small rounded belly and is provided with a delicate tendon which may fuse with the principal tendon or may be inserted into the capsule and the fascia in front of the fetlock joint.

Relations.—The chief relations of the belly of the muscle are: superficially, the skin and fascia; deeply, the elbow joint, the radius and ulna, the extensor carpi obliquus, and the anterior radial vessels and radial nerve; in front and internally, the extensor carpi radialis; behind, the lateral extensor and the interosseous vessels.

Blood-supply.—Radial and interosseous arteries.

Nerve-supply.—Radial nerve.

3. =Lateral digital extensor= (M. extensor digitalis lateralis s. digiti quinti proprius; lateral extensor of the phalanges; extensor suffraginis).—This muscle is much smaller than the preceding, behind which it is situated.

Origin.—The external tuberosity of the radius and the lateral ligament of the elbow joint, the shaft of the ulna, the outer border of the radius, and the intermuscular septum.

Insertion.—An eminence on the front of the proximal extremity of the first phalanx.

Action.—To extend the digit and carpus.

Structure.—The muscle is pennate, and is inclosed in a sheath formed by the deep fascia, from which many fibers arise. The belly is thin and fusiform and terminates at the lower third of the forearm. From here the tendon (at first small and round) passes downward through the groove on the outer tuberosity of the distal end of the radius, then over the carpus, and, gradually inclining toward the front, but not reaching the middle line of the limb, it passes over the metacarpus and fetlock to its insertion. Two =synovial membranes= occur in connection with the tendon. A =sheath= envelops the tendon, beginning about three inches (ca. 6 to 8 cm.) above the carpus, and reaching to the proximal end of the metacarpus. At the fetlock a small bursa lies between the tendon and the joint capsule, but otherwise the tendon is adherent to the capsule. The tendon becomes flat and much larger below the carpus, having received the tendon of the radial head of the anterior extensor and a strong band from the accessory carpal bone.

[Illustration:

FIG. 191.—MUSCLES OF LEFT THORACIC LIMB OF HORSE FROM ELBOW DOWNWARD; EXTERNAL VIEW.

_a_, Extensor carpi radialis; _g_, brachialis; _g′_, anterior superficial pectoral; _c_, anterior or common digital extensor; _e_, flexor carpi externus. (After Ellenberger-Baum, Anat. für Künstler.)]

Relations.—Superficially, the skin and fascia; deeply, the outer face of the radius and ulna; in front, the common extensor, the oblique extensor, and the interosseous artery; behind, the external flexor of the carpus and the deep flexor of the digit.

Blood-supply.—Interosseous artery.

Nerve-supply.—Radial nerve.

4. =Extensor carpi obliquus= (M. abductor pollicis longus et extensor pollicis brevis; oblique extensor of the metacarpus; extensor metacarpi obliquus).—This is a small muscle which curves obliquely over the distal half of the radius and the carpus.

Origin.—The external border and adjacent part of the anterior surface of the radius (the attachment area beginning at a point above the middle of the bone and extending down to its lower fourth).

Insertion.—The head of the inner (second) metacarpal bone.

Action.—To extend the carpal joint.

Structure.—The muscle is pennate and has a flat belly which curves downward, forward, and inward over the distal part of the radius. The tendon continues the direction of the muscle, crossing obliquely over the tendon of the extensor carpi radialis; it then occupies the oblique groove at the distal end of the radius, and crosses the inner face of the carpus. It is provided with a =synovial sheath=.

[Illustration:

FIG. 192.—CROSS-SECTION OF MIDDLE OF RIGHT FOREARM OF HORSE.

_a_, Accessory cephalic vein; _b_, cutaneous branch of median nerve; _c_, extensor carpi obliquus; _d_, posterior radial artery; _e_, satellite vein; _f_, median nerve; _g_, _g′_, ulnar vessels; _h_, ulnar nerve; _i_, cephalic vein; _k_, tendon of ulnar head of deep flexor; _l_, interosseous artery; _m_, extensor carpi radialis; _n_, anterior digital extensor; _o_, lateral digital extensor; _p_, flexor carpi externus; _q_, _q_, _q_, humeral heads of deep digital flexor; _r_, radial head of same; _s_, superficial digital flexor; _t_, flexor carpi medius; _u_, flexor carpi internus; _v_, radius; _w_, skin; _x_, anterior radial artery. (After Ellenberger, in Leisering’s Atlas.)]

Relations.—Superficially, the skin and fascia, the lateral extensor, and the common extensor; deeply, the radius, the extensor carpi radialis, the carpal capsule, and the internal lateral ligament.

Blood-supply.—Interosseous and anterior radial arteries.

Nerve-supply.—Radial nerve.

B. FLEXOR DIVISION

1. =Flexor carpi internus= (M. flexor carpi radialis s. radialis volaris; internal flexor of the metacarpus).—This muscle lies on the inner surface of the forearm, immediately behind the inner border of the radius.

Origin.—The flexor (internal) epicondyle of the humerus, below and behind the lateral ligament.

Insertion.—The proximal end of the internal (second) metacarpal bone.

Action.—To flex the carpal joint and to extend the elbow.

Structure.—The muscle has a short tendon of origin, which is succeeded by a somewhat flattened, fusiform belly. The tendon of insertion begins near the distal fourth of the radius. It is provided with a synovial sheath which begins two or three inches (ca. 5 to 8 cm.) above the carpus and extends almost to the insertion of the tendon.

Relations.—Superficially, the skin and fascia, the posterior superficial pectoral and the tensor fasciæ antibrachii; deeply, the elbow joint, the radius, the deep flexor, the flexor carpi medius, the posterior radial vessels, and the median nerve. At the elbow the artery and nerve lie in front of the muscle, but below they dip beneath it.

Blood-supply.—Posterior radial artery.

Nerve-supply.—Median nerve.

On removing the deep fascia on the inner surface of the elbow the student may notice a small muscle lying along the lateral ligament. This is the =pronator teres=, which is usually not present or a mere vestige in the horse. It arises by a small, flat tendon from the flexor epicondyle of the humerus, and is inserted into the internal lateral ligament of the elbow. On account of its small size and the fact that the forearm is fixed in the position of pronation, the muscle can have no appreciable function. It is usually represented by the long portion of the internal lateral ligament.

2. =Flexor carpi medius= (M. flexor carpi ulnaris s. ulnaris medialis; oblique or middle flexor of the metacarpus).—This muscle lies on the inner and posterior aspect of the forearm partly under, partly behind, the preceding muscle. It arises by two heads—humeral and ulnar.

Origin.—(1) The flexor (internal) epicondyle of the humerus just behind the preceding muscle; (2) the inner surface and posterior border of the olecranon.

Insertion.—The upper edge of the accessory carpal (pisiform) bone.

Action.—To flex the carpal joint, and to extend the elbow.

Structure.—The humeral head is much the larger, constituting, in fact, the bulk of the muscle. It is flattened, curved, and tapers at both ends. The ulnar head, much smaller and very thin, is covered by an aponeurosis from which many of its fibers arise. It joins the large head a little above the middle of the forearm. The tendon of insertion is short and strong; it blends with the posterior annular ligament of the carpus.

Relations.—Superficially, the tensor fasciæ antibrachii, superficial pectoral, and flexor carpi internus, the skin and fascia, and cutaneous branches of the ulnar nerve; deeply, the superficial and deep flexors of the digit. In the distal half of the forearm the ulnar vessels and nerve lie between the outer edge of this muscle and the external flexor of the carpus.

Blood-supply.—Ulnar and posterior radial arteries.

Nerve-supply.—Ulnar and median nerves.

[Illustration:

FIG. 193.—DEEPER MUSCLES OF FOREARM OF HORSE, INTERNAL VIEW.

_23_, Internal head of triceps; _30_, flexor carpi medius; _31_, flexor carpi internus; _31′_, tendon of _31_; _32_, superficial digital flexor; _32′_, radial check ligament; _32″_, tendon of superficial flexor; _33a_, _33b_, _33c_, humeral heads of deep flexor; _33′_, deep flexor tendon; _33″_, subcarpal check ligament; _34_, ulnar head of deep flexor; _35_, radial head of deep flexor; _36_, suspensory ligament. (After Ellenberger, in Leisering's Atlas.)]

3. =Flexor carpi externus= (M. extensor carpi ulnaris[61] s. ulnaris lateralis; external flexor of the metacarpus).—This muscle lies on the outer face of the forearm, behind the lateral extensor of the digit.

Origin.—The extensor (external) epicondyle of the humerus, behind and below the lateral ligament.

Insertion.—(1) The outer surface and upper edge of the accessory carpal bone; (2) the proximal extremity of the outer (fourth) metacarpal bone.

Action.—To flex the carpal joint and to extend the elbow.

Structure.—The belly of the muscle is flattened and is intersected by a good deal of tendinous tissue. There are two tendons of insertion. The short tendon is inserted into the accessory carpal bone. The long tendon is detached just above the carpus; it is smaller and rounded; it passes downward and a little forward through a groove on the outer surface of the accessory carpal bone, enveloped by a =synovial sheath=, to reach its insertion on the outer metacarpal bone. A synovial pouch lies under the origin of the muscle at the elbow joint, with the cavity of which it communicates.

[Illustration:

FIG. 194.—CROSS-SECTION OF PROXIMAL PART OF LEFT CARPUS OF HORSE.

The tendons have been removed to show the canals in which they lie. The joint cavity is black. By an oversight the carpal canal for the two flexor tendons behind the posterior ligament of the carpus is not marked. _Cr_, Radial, _Ci_, intermediate, _Cu_, ulnar, _Ca_, accessory carpal bones.]

Relations.—Superficially, the skin, fascia, and cutaneous branches of the ulnar nerve; deeply, the elbow joint, the ulna, and the flexors of the digit; in front, the lateral extensor of the digit; behind, the middle flexor of the carpus, the ulnar head of the deep flexor, and the ulnar vessels and nerve.

Blood-supply.—Interosseous, ulnar, and median arteries.

Nerve-supply.—Radial nerve.

4. =Superficial digital flexor= or =flexor perforatus= (M. flexor digitalis sublimis; superficial flexor of the phalanges).—This muscle is situated in the middle of the flexor group, chiefly under cover of the middle flexor of the carpus.

Origin.—(1) The flexor epicondyle of the humerus, between the flexor carpi internus and the deep flexor of the digit; (2) a ridge on the posterior surface of the radius, below its middle and near the internal border.

Insertion.—(1) The eminences on the proximal extremity of the second phalanx behind the lateral ligaments; (2) the distal extremity of the first phalanx, also behind the lateral ligaments.

Action.—To flex the digit and carpus, and to extend the elbow.

[Illustration:

(After Ellenberger, in Leisering's Atlas.)

The synovial sheaths (colored yellow) and the joint capsules (colored pink) are injected.]

[Illustration:

FIG. 196.—SYNOVIAL SHEATHS AND BURSÆ OF LOWER PART OF RIGHT FORE LIMB OF HORSE, EXTERNAL VIEW.

_a_, Sheath of extensor carpi radialis; _b_, sheath of anterior extensor; _c_, sheath of lateral extensor; _d_, sheath of outer tendon of flexor carpi externus; _e_, _e′_, carpal sheath; _f_, _f′_ _f″_, digital sheath; _g_, bursa under anterior extensor tendon; _h_, bursa under lateral extensor tendon; _i_, capsule of fetlock joint; _1_, extensor carpi radialis; _2_, anterior digital extensor; _3_, lateral digital extensor; _4_, flexor carpi externus; _4′_ _4″_, tendons of _4_; _5_, superficial flexor tendon; _6_, deep flexor tendon; _7_, suspensory ligament; _8_, external metacarpal bone; _9_, large metacarpal bone; _10_, posterior annular ligament of fetlock; _11_, digital annular ligament; _12_, fetlock joint; _13_, lateral cartilage; _14_, band from first phalanx to lateral cartilage. (After Ellenberger, in Leisering's Atlas.)]

Structure.—The fleshy portion of the muscle or =humeral head= takes origin from the humerus. The =radial head= (Caput tendineum) consists of a strong fibrous band, usually termed the =radial= or =superior check ligament=, which fuses with the tendon near the carpus. The belly of the muscle is intersected by tendinous strands, and fuses more or less with that of the deep flexor. Near the carpus it is succeeded by a strong, thick tendon which passes down through the carpal canal, formed by the posterior ligament of the carpus, the accessory carpal bone, and the posterior annular ligament (Ligamentum carpi transversum). Here it is enveloped by a synovial sheath, in common with the deep flexor. This =carpal sheath= (Vagina carpea) begins three or four inches (8 to 10 cm.) above the carpus, and extends downward nearly to the middle of the metacarpus. Below the carpus the tendon becomes flattened and broader. Near the fetlock it forms a ring through which the tendon of the deep flexor passes (Fig. 150). Here the two tendons are bound down in the sesamoid groove by the posterior annular ligament, which fuses more or less with the superficial flexor tendon. At the distal end of the first phalanx the tendon divides into two branches which diverge to reach

their points of insertion, and between these branches the tendon of the deep flexor emerges (Fig. 189). A second =synovial sheath=, the =digital= or =sesamoidean= (Vagina digitalis), begins at the distal third of the metacarpus, three to four inches (8 to 10 cm.) above the fetlock, and extends to the middle of the second phalanx.

[Illustration:

FIG. 197.—CROSS-SECTION OF DISTAL PART OF LEFT METACARPUS OF HORSE, JUST ABOVE SESAMOIDS.]

Relations.—The belly of the muscle is related superficially to the ulnar head of the deep flexor, the flexor carpi medius, and, at its origin, to the ulnar vessels and nerve; deeply to the humeral head of the deep flexor. The tendon is related superficially to the skin and fascia; deeply to the deep flexor tendon.

Blood-supply.—Posterior radial artery.

Nerve-supply.—Median nerve.

5. =Deep digital flexor= or =flexor perforans= (M. flexor digitalis profundus; deep flexor of the phalanges).—The fleshy part of this muscle lies on the posterior surface of the radius, under cover of the preceding muscles. It is the largest muscle of the flexor group.

Origin.—(1) The flexor (internal) epicondyle of the humerus; (2) the inner surface of the olecranon; (3) the middle of the posterior surface of the radius and a small adjacent area of the ulna.

Insertion.—The semilunar crest of the third phalanx, and the adjacent surface of the lateral cartilage.

Action.—To flex the digit and carpus, and to extend the elbow.

Structure.—This muscle consists of three principal heads. The =humeral head= (Caput humerale) constitutes the bulk of the muscle. It is marked by tendinous intersections, and is separable into three secondary heads. The =ulnar head= (Caput ulnare, ulnaris accessorius) is much smaller, and is at first superficially situated between the outer and middle flexors of the carpus, the =radial head= (Caput radiale, radialis accessorius) is the smallest, and is not always present; it is situated on the distal two-thirds of the posterior surface of the radius, under the humeral head. Each of these heads is provided with a tendon. The principal tendon—that of the humeral head—begins about three or four inches (8 to 10 cm.) above the carpus. It is soon joined by the small tendon of the ulnar head, which begins about the middle of the forearm. The tendon of the radial head fuses with the principal tendon close to the carpus. The conjoined tendon passes downward through the carpal canal, being included in the =carpal synovial sheath= with the superficial flexor tendon, as previously described. Continuing downward, it is joined about the middle of the metacarpus by a strong fibrous band, the so-called =inferior= or =subcarpal check ligament= (Caput tendineum). This is a direct continuation of the posterior ligament of the carpus. Below this the tendon passes through the ring formed by the perforatus, then in succession over the sesamoid groove, the inferior sesamoidean ligaments, and the tendon surface of the third sesamoid, to its insertion (Figs. 150 and 151). Its terminal part is much widened. From the distal third of the metacarpus to the distal end of the second phalanx it is inclosed in the =digital synovial sheath= described in connection with the perforatus. The =navicular bursa= or =bursa podotrochlearis= is found between the tendon and the third sesamoid or navicular bone. The terminal part of the tendon is bound down by the fibrous sheet described with the fascia.

[Illustration:

FIG. 198.—DIGIT OF HORSE, LATERAL VIEW.

_1_, Large metacarpal bone; _2_, distal end of small metacarpal bone; _3_, fetlock joint; _5_, first phalanx; _6_, pastern joint; _7_, second phalanx; _8_, coffin joint; _9_, third phalanx; _11_, lateral cartilage; _11′_, upper (subcutaneous) border of cartilage; _12_, suspensory ligament; _13_, branch of _12_ to extensor tendon; _14_, deep flexor tendon; _15_, superficial flexor tendon; _15′_, branch of _15_; _16_, posterior annular ligament of fetlock; _17_, proximal annular or vaginal ligament of digit; _18_, distal annular ligament or reinforcing sheath of deep flexor tendon; _19_, lateral ligament of coffin joint; _21_, tendon of common or anterior extensor; _22_, tendon of lateral extensor; _23_, digital vein. (After Ellenberger-Baum, Anat. für Künstler.)]

Relations.—The belly of the muscle is related posteriorly to the perforatus and the middle flexor of the carpus; internally, to the internal carpal flexor, the radial check ligament, and the posterior radial vessels and median nerve; externally, to the external flexor of the carpus; anteriorly, to the radius and ulna and branches of the posterior radial artery and median nerve. Below the carpus the tendon is accompanied by the vessels and nerves of the digit. It may also be noted that the muscle is not entirely covered by the

other flexors; it comes in contact with the skin and fascia on the postero-external aspect of the proximal half of the forearm, and also on the outer aspect of the distal fourth.

Blood-supply.—Posterior radial and ulnar arteries.

Nerve-supply.—Median and ulnar nerves.

METACARPAL MUSCLES

The five muscles of this group are either reduced to vestiges or modified greatly in structure.

1, 2. =Lumbricales= (internus et externus).—These are two small muscles which lie on either side of the flexor tendons above the fetlock. They arise from the deep flexor tendon, and are lost in the fibrous tissue which lies under the nodule of horn or ergot at the fetlock (Fig. 447). Their action is inappreciable. The size of these muscles is subject to much variation. Often very little muscular tissue can be found, but the small tendon is constantly present.

Blood-supply.—Metacarpal arteries.

Nerve-supply.—Median and ulnar nerves.

3, 4, 5. =Interossei.=—These are three in number in the horse, and are situated chiefly in the metacarpal groove. Two, the =internus= and =externus=, are very small muscles, each of which arises from the corresponding small metacarpal bone near its proximal extremity, and is provided with a delicate tendon which is usually lost in the fascia at the fetlock (Fig. 150). They have no appreciable action. Their blood- and nerve-supply is the same as that of the preceding muscles.

The =interosseus medius= is so much modified that it is usually termed the =suspensory=, or =superior sesamoidean ligament=. It contains little muscular tissue, being transformed very largely into a strong tendinous band, bifurcate below, and having for its chief function the supporting of the fetlock. It has been described, in deference to common usage, with the ligaments.

FASCIÆ AND MUSCLES OF THE PELVIC LIMB

THE FASCIÆ

The =iliac fascia= (Fascia iliaca) covers the ventral surface of the iliacus and psoas muscles, over which it is tightly stretched (Fig. 450). It is attached internally to the tendon of the psoas minor, externally to the inguinal (Poupart's) ligament and the external angle of the ilium. Its anterior part is thin. Posteriorly, it is in part attached to the ilium, in part becomes continuous with the pelvic fascia. It furnishes surfaces of origin for the sartorius, cremaster externus, and transversus abdominis muscles.

The =pelvic fascia= (Fascia pelvis) lines the cavity (parietal layer) and is reflected on the viscera at the pelvic outlet (visceral layer). Laminæ are detached from it to strengthen the various peritoneal folds.

The =superficial fascia= of the =gluteal region= is continuous with the aponeurosis of the panniculus. It covers and partly blends with the deep fascia. The =gluteal fascia= (Fascia glutea) covers the superficial muscles of the region, and detaches intermuscular septa, which pass between the muscles. It is attached to the sacral spines, the dorsal sacro-iliac ligament, and the angles of the ilium, and is continuous in front with the lumbo-dorsal fascia, behind with the coccygeal fascia. Its deep face gives origin to fibers of the superficial and middle glutei, the biceps femoris, and the semitendinosus, so that care is necessary in dissecting it off these muscles. The chief =intermuscular septa= are: (1) One which passes between the superficial gluteus and the biceps femoris; (2) one between the biceps and semitendinosus, from which a lamella is detached which passes between the middle and posterior portions of the biceps and is attached to the tuber ischii; (3) one between the semitendinosus and semimembranosus, which is attached to the sacro-sciatic ligament and tuber ischii; it furnishes origin for fibers of the long head of the semimembranosus.

The =fascia lata= is continuous with the preceding, and covers the muscles on the outer surface and front of the thigh. It is tendinous and very strong, and for the most part easily separable from the underlying muscles. It furnishes insertion to the tensor fasciæ latæ and to the biceps femoris (in part), by both of which it is tensed. At the stifle it is attached to the patella and the inner and outer straight ligaments. Internally it is continuous with the internal femoral fascia. It furnishes the following =intermuscular septa=: (1) One which passes between the vastus externus and biceps femoris to be attached to the external trochanter of the femur; (2) two which pass between the three branches of the biceps femoris; (3) a fourth between the biceps femoris and

semitendinosus.

The =internal femoral fascia= (Fascia femoralis medialis) covers the superficial muscles on the inner surface of the thigh. At its upper part it is joined by part of the aponeurosis of the external oblique muscle (Lamina femoralis) (Fig. 450). The posterior part is thin. It is continuous with the fascia lata in front and the crural fascia below. At the stifle it fuses with the tendons of the sartorius and gracilis.

The =crural fascia=, or fascia of the leg (Fascia cruris), consists of three layers. Two of these invest the entire region and may, therefore, be termed the =common fasciæ=. The superficial layer is a continuation of the fasciæ of the thigh, while the second layer may be regarded chiefly as a continuation of the tendons of the superficial muscles of the hip and thigh (biceps femoris, semitendinosus, tensor fasciæ latæ, sartorius, and gracilis). The two layers frequently fuse, and are attached chiefly to the patellar ligaments and the crest and internal surface of the tibia. About the middle of the leg the two layers unite behind the deep flexor of the digit and form a strong band which passes downward in front of the tendons of the gastrocnemius and superficial flexor, to be attached with the latter to the anterior and inner part of the tuber calcis. This may be regarded as an accessory or tarsal tendon of insertion of the biceps femoris and semitendinosus. The third layer forms sheaths for the muscles, furnishing origin in part to their fibers. Two important =intermuscular septa= are detached, viz.: (1) One which passes between the anterior and lateral digital extensors to be attached to the fibula and the external border of the tibia; (2) one between the lateral extensor and the deep flexor.

The =tarsal fascia= (Fascia tarsi) fuses with the ligaments and bony prominences of the region. It is strong and tendinous in front, and joins the tendon of the anterior extensor below the joint. Laterally, it is thin and fuses with the ligaments. Posteriorly, it is very thick and strong, forming an annular ligament which stretches from the internal lateral ligament to the fibular tarsal bone and the plantar ligament. This converts the groove at the back of the hock into a canal, in which are the deep flexor tendon with its synovial sheath and the plantar nerves. In front of the tarsus and above and below it there are three =annular ligaments= (Ligamenta transversa). The proximal one binds down the tendons of the anterior extensor, peroneus tertius, and tibialis anterior on the distal end of the tibia. The middle one stretches from the fibular tarsal bone to the outer tendon of the peroneus tertius, forming a loop around the tendon of the anterior extensor. The distal band stretches across the proximal extremity of the large metatarsal bone and incloses the tendons (and sheaths) of the two extensors of the digit.

The =metatarsal= and =digital fasciæ= do not differ materially from those of the corresponding regions of the thoracic limb.

THE MUSCLES

I. THE SUBLUMBAR MUSCLES (Figs. 450, 456)

The muscles of this group are not confined to the sublumbar region, but extend beyond it both before and behind. Their chief function is to flex the hip joint. Two, however,—the psoas minor and the quadratus lumborum,—have not this action.

1. =Psoas minor= (s. parvus).—This is a fusiform, flattened, pennate muscle, which lies along the ventro-lateral aspect of the bodies of the last three thoracic and the lumbar vertebræ.

Origin.—The bodies of the last three thoracic and first four or five lumbar vertebræ, and the vertebral ends of the sixteenth and seventeenth ribs.

Insertion.—The psoas tubercle on the shaft of the ilium.

Action.—To flex the pelvis on the loins, or to incline it laterally.

Structure.—The muscle arises by a series of digitations which pass backward and outward to be inserted at an acute angle on the tendon. The latter lies along the outer border of the fleshy portion and is flattened. It appears on the surface of the muscle at the third lumbar process and increases gradually in width until it reaches the pelvic inlet, where it becomes narrower.

Relations.—The ventral surface of the thoracic portion of the muscle is related to the pleura, crura of the diaphragm, and sympathetic nerve. In the abdomen, the chief ventral relations are the peritoneum, the vena cava (right side), the aorta and left kidney (left side), the sympathetic nerves, and the ureters. Dorsally, the chief relations are the vertebræ, the psoas major, and lumbar nerves. Near its insertion the tendon is crossed internally by the external iliac artery, and externally by the femoral nerve.

Blood-supply.—Intercostal and lumbar arteries.

Nerve-supply.—Lumbar nerves.

2. =Psoas major= (s. magnus).—This is much larger than the preceding muscle, by which it is partly covered. It is triangular, with the base anterior.

Origin.—The ventral surfaces of the vertebral ends of the last two ribs and the transverse processes of the lumbar vertebræ.

Insertion.—The internal trochanter of the femur, by a common tendon with the iliacus.

Action.—To flex the hip joint and to rotate the thigh outward.

Structure.—The origin of the muscle is fleshy, the belly being in general flattened, thick in its middle, thin at its edges. The thoracic portion is small, the abdominal part much thicker and wider, extending laterally beyond the extremities of the lumbar transverse processes. From the lumbo-sacral articulation it lies in a deep groove formed in the iliacus (with which it is partly united), becomes smaller and rounded, and passes downward and backward to terminate by a strong tendon common to it and the iliacus.[62]

Relations.—Dorsally, the last two ribs and thoracic vertebræ, the lumbar vertebræ, the internal intercostals, quadratus lumborum, longissimus dorsi, and iliacus, and the lumbar vessels and nerves; ventrally, the pleura and peritoneum, the iliac fascia, inguinal ligament, the diaphragm, psoas minor, and sartorius, the kidneys, the spleen, the intestine (duodenum, cæcum, etc.) and the circumflex iliac vessels.

Blood-supply.—Lumbar and circumflex iliac arteries.

Nerve-supply.—Lumbar and femoral nerves.

3. =Iliacus.=—This muscle covers the ventral surface of the ilium external to the sacro-iliac articulation, and extends outward beyond the external border of the bone, underneath the middle gluteus.

Origin.—The ventral surface of the ilium external to the ilio-pectineal line, the ventral sacro-iliac ligament, the wing of the sacrum, and the tendon of the psoas minor.

Insertion.—The internal trochanter of the femur, by a common tendon with the psoas major.

Action.—To flex the hip joint and to rotate the thigh outward.

Structure.—The belly of the muscle is so deeply grooved for the psoas major as to give the appearance of being completely divided into outer and inner portions. When the psoas is removed, it is seen, however, that the two heads are not entirely separated. The outer, larger head arises from the wing of the ilium chiefly; the inner, smaller head arises chiefly from a small area on the shaft of the ilium, between the psoas tubercle and the depression for the inner tendon of the rectus femoris, and from the tendon of the psoas minor. The two portions inclose the psoas major in front of the hip joint.

Relations.—Dorsally, the ilium, sacrum, sacro-iliac articulation, the gluteus medius, the ilio-lumbar and external circumflex vessels; ventrally, the iliac fascia, inguinal ligament, the psoas major, sartorius, and abdominal muscles. At the hip joint the chief relations are: internally, the femoral vessels, the femoral nerve, and the sartorius muscle; externally, the rectus femoris and tensor fasciæ latæ; in front, the abdominal muscles; behind, the hip joint.

Blood-supply.—Lumbar, circumflex iliac, and deep femoral arteries.

Nerve-supply.—Lumbar and femoral nerves.

4. =Quadratus lumborum.=—This thin muscle lies on the outer part of the ventral surfaces of the lumbar transverse processes.

Origin.—The ventral surface of the upper part of the last two ribs and the lumbar transverse processes.

Insertion.—The ventral surface of the wing of the sacrum and the ventral sacro-iliac ligament.

Action.—Acting together, to fix the last two ribs and the lumbar vertebræ; acting singly, to produce lateral flexion of the loins.

Structure.—The muscle is pennate, and is curved with the convexity outward. It is thin, largely mixed with tendinous fibers, and is, in general, little developed in the horse in comparison with some of the other animals (_e. g._, dog, sheep).

Relations.—Ventrally, the psoas major and the last intercostal and first three lumbar nerves; dorsally, the last two ribs, the lumbar transverse processes, and the lateral branches of the lumbar arteries.

Blood-supply.—Lumbar arteries.

Nerve-supply.—Lumbar nerves.

5. =Intertransversales lumborum= (M. intertransversarii lumborum).—These are described with the other spinal muscles. (See p. 238.)

II. THE EXTERNAL MUSCLES OF THE HIP AND THIGH

Under this head will be described the muscles of the outer surface of the pelvis and thigh, and those which form the posterior contour of the latter. They are given in the order in which they may be conveniently examined.

1. =Tensor fasciæ latæ= (Fig. 178).—This is the most anterior muscle of the superficial layer. It is triangular in form, with its apex at the external angle of the ilium.

Origin.—The external angle of the ilium.

Insertion.—The fascia lata, and thus indirectly to the patella, the external straight ligament, and the crest of the tibia.

Action.—To tense the fascia lata, flex the hip joint, and extend the stifle joint.

Structure.—The muscle arises by a rather small head, about two inches (ca. 5 cm.) wide, on the antero-inferior eminence of the external angle of the ilium. Below this the belly spreads out and terminates about midway between the point of the hip and the stifle in the aponeurosis. The belly fuses to a considerable extent with the superficial gluteus. The aponeurosis fuses with the fascia lata, and detaches a lamina which passes with the tendon of insertion of the superficial gluteus to the external border of the femur.

Relations.—Externally, the skin and fascia; internally, the obliquus abdominis externus, the iliacus, superficial gluteus, rectus femoris, and vastus externus, branches of the circumflex iliac, ilio-lumbar, and iliaco-femoral arteries, and the anterior gluteal nerve; anteriorly, the precrural lymph glands. A considerable quantity of connective tissue is found between the deep face of the muscle and the abdominal wall.

Blood-supply.—Circumflex iliac, ilio-lumbar, and iliaco-femoral arteries.

Nerve-supply.—Anterior gluteal nerve.

2. =Gluteus superficialis= (Figs. 178, 199) (Superficial gluteus; gluteus externus).—This muscle lies behind and partly underneath the tensor fasciæ latæ. It is triangular and consists of an anterior and a posterior head united by the gluteal fascia.

Origin.—(1) The external angle and the adjacent part of the external border of the ilium (anterior head); (2) the gluteal fascia (posterior head).

Insertion.—The third (external) trochanter of the femur.

Action.—To abduct the limb, flex the hip joint, and tense the gluteal fascia.

Structure.—The anterior head of the muscle is not completely separable (except artificially) from the tensor fasciæ latæ. The attachment to the border of the ilium is by means of an intermuscular septum, which passes beneath the thick outer border of the gluteus medius. The posterior head arises from the deep face of the gluteal fascia, and so indirectly from the dorsal sacro-iliac ligament. The two heads unite and terminate on a strong flat tendon, which is inserted into the edge of the third trochanter of the femur, beneath the biceps femoris.

Relations.—Superficially, the skin, fascia, and biceps femoris; deeply, the gluteus medius, iliacus, rectus femoris, and branches of the iliaco-femoral artery; in front, the tensor fasciæ latæ; behind, the biceps femoris.

Blood-supply.—Gluteal and iliaco-femoral arteries.

Nerve-supply.—Anterior gluteal nerve.

3. =Gluteus medius= (Figs. 178, 179) (Middle gluteus; gluteus maximus).—This is a very large muscle which covers the dorsal surface of the ilium and the greater part of the lateral wall of the pelvis, and extends forward also on the lumbar part of the longissimus.

Origin.—(1) The aponeurosis of the longissimus, as far forward as the first lumbar vertebra; (2) the gluteal or dorsal surface and internal and external angles of the ilium; (3) the dorsal and lateral sacro-iliac and sacro-sciatic ligaments, and the gluteal fascia.

Insertion.—(1) The summit of the trochanter major of the femur; (2) the crest below the trochanter; (3) the outer aspect of the trochanteric ridge.

Action.—To extend the hip joint and abduct the limb. By its connection with the longissimus a muscular mass is formed which is one of the chief factors in rearing, kicking, and propulsion.

Structure.—The anterior extremity of the muscle is relatively thin, and lies in a depression on the surface of the longissimus, from the strong aponeurosis of which the fibers take origin. The pelvic portion of the muscle is very voluminous, and forms the bulk of the muscular mass which gives the haunch its rounded contour. This part of the muscle is intersected by several tendinous sheets. One of these is particularly distinct, and is attached to the gluteal line on the ilium. This divides the muscle incompletely into superficial and deep strata. The superficial part is inserted by a strong tendon into the summit of the great trochanter, and by a pointed fleshy mass with a tendinous border into the trochanteric ridge. The deep part (Gluteus accessorius) is smaller, and arises entirely from the ilium between the gluteal line and the external angle (Fig. 455). It has a strong flat tendon which passes over the convexity of the trochanter to be inserted into the crest below it. The convexity is covered with cartilage, and the =trochanteric bursa= (Bursa trochanterica) is interposed between the tendon and the cartilage.[63]

Relations.—Superficially, the skin, lumbo-dorsal and gluteal fasciæ, the tensor fasciæ latæ, gluteus superficialis, and biceps femoris; deeply, the longissimus, the ilium, sacro-iliac and sacro-sciatic ligaments, the gluteus profundus, iliacus and rectus femoris, the iliaco-femoral artery, the gluteal and internal pudic vessels and nerves, and the great sciatic nerve.

Blood-supply.—Gluteal, ilio-lumbar, lumbar, and iliaco-femoral arteries.

Nerve-supply.—Gluteal nerves.

4. =Gluteus profundus= (Deep gluteus; gluteus internus; scansorius).—This much smaller, quadrilateral muscle lies under the posterior part of the preceding muscle, and extends over the hip joint, from the superior ischiatic spine to the anterior part of the great trochanter (Fig. 455).

Origin.—The superior ischiatic spine and the adjacent part of the shaft of the ilium.

Insertion.—The edge of the anterior part or convexity of the trochanter major of the femur.

Action.—To abduct the thigh and to rotate it inward.

Structure.—The muscle is short and thick and contains numerous tendinous intersections. The fibers are directed almost transversely outward over the capsule of the hip joint and converge at the convexity of the trochanter.

Relations.—Superficially, the gluteus medius and branches of the gluteal vessels and nerves; deeply, the shaft of the ilium, the hip joint, and the rectus femoris and capsularis.

Blood-supply.—Gluteal artery.

Nerve-supply.—Anterior gluteal nerve.

5. =Biceps femoris= (Gluteo-biceps s. paramero-biceps).—This large muscle lies behind and in part upon the superficial and middle glutei. It extends in a curved direction from the sacral and coccygeal spines to the outer surface of the stifle and leg (Figs. 178, 199, 200, 201, 202).

Origin.—(1) The dorsal sacro-iliac ligament, the gluteal and coccygeal fasciæ, and the intermuscular septum between this muscle and the semitendinosus; (2) the tuber ischii.

Insertion.—(1) A tubercle on the posterior surface of the femur near the external trochanter; (2) the anterior surface and external straight ligament of the patella; (3) the tibial crest; (4) the anterior and internal surface of the tuber calcis.

Action.—The action is somewhat complex, because the muscle is composed of three portions, has several points of insertion, and acts on all the joints of the limb except those of the digit. The general action is to extend the limb, as in propelling the body, rearing or kicking, and to abduct it. The anterior part, by its attachment to the posterior surface of the femur and to the patella, would extend the stifle and hip joints and abduct the limb. The middle part, being inserted chiefly on the tibial crest and the external straight ligament, would extend the hip, and, with the semitendinosus, flex the stifle. The posterior part, by virtue of its attachment to the tuber calcis, assists in extending the hock.

[Illustration:

FIG. 199.—MUSCLES OF PELVIC LIMB OF HORSE, POSTERO-EXTERNAL VIEW.

_17_, Position of tuber ischii; _o′_, superficial gluteus; _q_, _q′_, _q″_, biceps femoris; _r_, semitendinosus; _t_, sacro-coccygeus lateralis; _v_, semimembranosus; _w_, gracilis; _f_, gastrocnemius. (After Ellenberger-Baum, Anat. f. Künstler.)]]

Structure.—The muscle has two heads of origin:[64] The long or vertebral head arises chiefly from the dorsal and lateral sacro-iliac ligaments, the coccygeal fascia, and the intermuscular septum. There is often a large =bursa= between this head and the trochanter major. The short or ischiatic head arises by a strong tendon from the ventral spine on the tuber ischii. They unite, and a short tendon is detached from the deep face of the muscle, to be inserted into the posterior surface of the femur near the third trochanter (Fig. 455), a =bursa= being interposed between the tendon and the bone. The muscle then divides into three portions, which terminate on a strong aponeurosis over the junction of the thigh and leg. The anterior branch is directed toward the patella, the middle toward the tibial crest, while the posterior one assists in the formation of the posterior contour of the limb. The aponeurosis blends with the deep layer of the fascia cruris, as already described. A synovial =bursa= occurs under the patellar insertion.

Relations.—Superficially, the skin and fascia; deeply, the sacro-iliac and sacro-sciatic ligaments, the coccygeal fascia, the femur, the obturator, gemellus, quadratus femoris, adductor, semimembranosus, vastus externus, and gastrocnemius muscles, branches of the lateral sacral, gluteal, obturator, femoral and deep femoral vessels, the great sciatic, tibial, peroneal, and posterior gluteal nerves; in front, the superficial and middle glutei; behind and internally, the semitendinosus.

Blood-supply.—Gluteal, obturator, and femoro-popliteal arteries.

Nerve-supply.—Posterior gluteal and great sciatic nerves.

6. =Semitendinosus= (Biceps rotator tibialis).—This is a long muscle which extends from the first two coccygeal vertebræ to the proximal third of the inner surface of the tibia. It lies at first behind the biceps, then passes downward on the back of the thigh, between that muscle and the semimembranosus (Figs. 178, 179, 199). It has two heads of origin.

Origin.—(1) The transverse processes of the first and second coccygeal vertebræ, the coccygeal fascia, and the intermuscular septum between this muscle and the biceps femoris; (2) the ventral surface of the tuber ischii.

Insertion.—(1) The tibial crest; (2) the crural fascia and the tuber calcis.

Action.—To flex the stifle and rotate the leg inward; also to extend the hip and hock joints, acting with the biceps and semimembranosus in propulsion of the trunk, rearing, etc.

Structure.—The long or vertebral head is small at its origin, but becomes larger by the accession of fibers arising on the intermuscular septum. Below the tuber ischii it is joined by the short head, which arises partly by fleshy fibers, partly by a common tendon with the biceps. The muscle then passes downward on the back of the thigh, and terminates on a wide tendon on the inner surface of the proximal third of the leg. A distinct band passes forward to be inserted on the tibial crest (a =bursa= lying between the tendon and the tibia), part fuses with the fascia of the leg, while the remainder joins the biceps tendon and concurs in the formation of the tendinous band, which, as before described, terminates on the tuber calcis (Fig. 458). A _bursa_ may occur under the long head where it passes over the tuber ischii.

Relations.—Externally, the skin and fascia, the biceps, and the internal head of the gastrocnemius; internally, the coccygeal fascia, the sacro-sciatic ligament, the semimembranosus; anteriorly, the biceps femoris, branches of the femoral artery, and the great sciatic nerve.

Blood-supply.—Posterior gluteal, obturator, and femoro-popliteal arteries.

Nerve-supply.—Posterior gluteal and great sciatic nerves.

7. =Semimembranosus=[65] (Figs. 179, 186, 199, 451).—This muscle lies on the inner surface of the preceding muscle and the gastrocnemius, and has two heads of origin.

Origin.—(1) The posterior border of the sacro-sciatic ligament; (2) the ventral surface of the tuber ischii.

Insertion.—The internal epicondyle of the femur, behind the lateral ligament.

Action.—To extend the hip joint and to adduct the limb.

Structure.—The long head, small and pointed above, extends toward the root of the tail, fusing with the sacro-sciatic ligament. Passing downward, it becomes larger and covers in part the posterior aspect of the tuber ischii. A =bursa= may be found here. Below this it joins the short head, which is much larger. The large belly so formed passes downward and forward, covered in great part by the gracilis, and terminates on a short, flat tendon of insertion at the distal end of the femur.

Relations.—The upper part of the muscle assists in forming the lateral boundary of the pelvic outlet. It is related posteriorly and externally to the skin and fascia and the semitendinosus; internally, to the anus and its muscles, the vulva in the female, and the internal pudic artery and nerve (Figs. 452, 453). Below the pelvis the chief relations are: externally, the semitendinosus, biceps, and gastrocnemius, branches of the obturator, femoral, and femoro-popliteal arteries, and the great sciatic nerve and its chief branches; internally, the crus penis and ischio-cavernosus muscle (in the male), and the gracilis; in front, the adductor and the femoral vessels; behind, the skin and fascia.

Blood-supply.—Obturator and femoral arteries.

Nerve-supply.—Great sciatic nerve.

IV. THE INTERNAL MUSCLES OF THE THIGH

The muscles of this group are arranged in three layers.

FIRST LAYER

1. =Sartorius= (Figs. 180, 202, 203).—This long and rather narrow muscle is the most anterior one of the first layer. It extends from the sublumbar region to the lower and inner part of the stifle.

Origin.—The iliac fascia and the tendon of the psoas minor.

Insertion.—The internal straight ligament of the patella and the adjacent part of the tuberosity of the tibia.

Action.—To flex the hip joint and adduct the limb.

Structure.—The muscle is very thin at its origin, but becomes thicker and narrower as it passes downward and a little backward. It terminates near the stifle joint on an aponeurosis which blends with that of the gracilis and with the fascia of the leg.

Relations.—Superficially, the inguinal (Poupart's) ligament, the abdominal muscles, the skin and fascia, and the saphenous vessels and nerve; deeply, the ilio-psoas, quadriceps femoris, and adductor. It forms the anterior boundary of the femoral canal, in which the femoral artery and vein and the deep inguinal lymph glands are situated (Fig. 451).

Blood-supply.—Femoral artery.

Nerve-supply.—Femoral and saphenous nerves.

2. =Gracilis= (Figs. 186, 199, 202, 203).—This is a wide, flat, quadrilateral muscle, situated behind the sartorius, which it exceeds greatly in extent.

Origin.—The middle third of the pelvic symphysis, the prepubic tendon and pubo-femoral ligament, and the ventral surface of the pubis behind the prepubic tendon.

Insertion.—The internal straight ligament of the patella, the internal surface of the tibia in front of the lateral ligament of the stifle joint, and the fascia of the leg.

Action.—To adduct the limb. It may also rotate it inward.

Structure.—The muscle arises by a strong tendon, chiefly in common with the opposite muscle. Its direct attachment to the ventral surface of the pelvis is not so extensive as a superficial inspection would suggest. The origin of the muscle presents anteriorly a round perforation for the passage of the external pudic vein. The belly is composed of parallel bundles, and is marked by a superficial furrow which, however, does not indicate a muscular division. It terminates on the inner surface of the stifle on a thin wide tendon which blends in front with that of the sartorius, below with the crural fascia.

Relations.—Superficially, the skin and fascia, the penis or mammary gland, and the saphenous vessels and nerve; deeply, the pectineus, adductor, semimembranosus and semitendinosus, and, at the middle of the femur, the femoral vessels; anteriorly, the sartorius. In the upper third of the thigh the sartorius and gracilis are separated by a triangular interval (femoral triangle), in which lie the deep inguinal lymph glands and the femoral vessels.

Blood-supply.—Femoral and deep femoral arteries.

Nerve-supply.—Obturator and saphenous nerves.

SECOND LAYER

1. =Pectineus= (Figs. 180, 451, 456).—This muscle is fusiform and extends from the anterior border of the pubis to the middle of the inner border of the femur.

Origin.—The prepubic tendon, the pubo-femoral ligament, and the anterior border of the pubis.

Insertion.—The middle of the internal border of the femur, near the nutrient foramen.

Action.—To adduct the limb and flex the hip joint.

Structure.—The belly is cylindrical and contains little fibrous tissue. Its origin is perforated by the pubo-femoral ligament, and is thus divided into two unequal parts. The large upper part arises mainly from the prepubic tendon—only a very small part gaining direct attachment to the pubis. The small lower part does not reach the bone. The insertion is pointed and tendinous.

Relations.—Superficially, the gracilis; deeply, the femur, the vastus internus, the terminal tendon of the psoas major and iliacus, and the deep femoral artery; anteriorly, the sartorius, the femoral vessels, the saphenous nerve, and the deep inguinal lymph glands; posteriorly, the adductor, obturator externus, and quadratus femoris, and the obturator nerve (anterior division).

Blood-supply.—Femoral and deep femoral arteries.

Nerve-supply.—Femoral and obturator nerves.

The _femoral canal_ is exposed in the dissection of the preceding muscles (Figs. 200, 451). It is bounded anteriorly by the sartorius, posteriorly by the pectineus, and externally by the iliacus and vastus internus. Its internal wall is formed by the femoral fascia and the gracilis. Its upper or abdominal opening (Lacuna vasorum) lies behind and a little internal to the internal inguinal ring and is bounded anteriorly by the inguinal ligament, posteriorly by the anterior border of the pubis, and externally by the tendon of the psoas minor. The canal terminates below at the insertion of the pectineus. It contains the deep inguinal lymph glands, the femoral artery and vein, and the saphenous nerve.

2. =Adductor=[66] (Figs. 179, 186, 451) (Great and small adductors of the thigh).—This fleshy, prismatic muscle lies behind the pectineus and vastus internus. It extends downward and forward from the ventral surface of the pelvis to the internal condyle of the femur.

Origin.—The ventral surface of the pubis and ischium and the tendon of the gracilis.

Insertion.—(1) The posterior surface of the femur from the level of the external trochanter to the groove for the femoral vessels; (2) the internal epicondyle of the femur and the internal lateral ligament of the stifle joint.

Action.—To adduct the limb and assist in extending the hip joint. It may also rotate the femur outward.

Structure.—It is almost entirely fleshy, and is composed of parallel bundles united rather loosely. It is usually possible to separate from the principal mass a small anterior short portion,[67] which is inserted into the femur behind the pectineus. The principal mass[68] is perforated below its middle by the femoral vessels, and is thus divided into two branches. The outer branch is inserted into the back of the femur with the short portion, while the inner branch is attached to the internal epicondyle and lateral ligament. There is often a superficial slip which reaches the internal straight patellar ligament. Some fibers pass under the lateral ligament and end on the tendon of the semimembranosus.

Relations.—Internally, the gracilis, and branches of the femoral artery and of the obturator nerve; externally, the femur, the obturator externus, quadratus femoris, biceps femoris, and gastrocnemius, and the femoral, deep femoral, and obturator arteries; anteriorly, the pectineus, vastus internus, and a large branch of the obturator nerve; posteriorly, the semimembranosus and the great sciatic nerve.

Blood-supply.—Femoral, deep femoral, and obturator arteries.

Nerve-supply.—Obturator nerve.

3. =Semimembranosus.=—Described on p. 280.

THIRD LAYER

1. =Quadratus femoris= (Ischio-femoralis).—This is a narrow, flat muscle, which lies under cover of the upper part of the adductor (Figs. 455, 456).

Origin.—The ventral surface of the ischium, just in front of the semimembranosus.

Insertion.—An oblique line on the posterior surface of the femur, near the lower part of the internal trochanter.

Action.—To extend the hip joint, and to adduct the thigh and rotate it outward.

Structure.—It is composed of parallel bundles of fibers directed downward, forward, and outward.

Relations.—Internally, the adductor, semimembranosus, and the obturator vessels; externally, the obturator externus and biceps femoris, the deep femoral artery, and the great sciatic nerve.

Blood-supply.—Deep femoral and obturator arteries.

Nerve-supply.—Great sciatic nerve.

2. =Obturator Externus= (Fig. 456).—This is a pyramidal muscle which extends across the back of the hip joint from the obturator foramen to the trochanteric fossa.

Origin.—The ventral surface of the pubis and ischium, and the margin of the obturator foramen.

Insertion.—The trochanteric fossa.

Action.—To adduct the thigh and to rotate it outward.

Structure.—It is almost entirely fleshy, the muscle-bundles being rather loosely connected. The insertion is pointed, flattened, and partly tendinous. The origin is perforated by the obturator vessels and nerve.

Relations.—Internally, the adductor and quadratus femoris and the deep femoral vessels; externally, the gemellus, the tendon of the obturator internus, the biceps femoris, and the great sciatic nerve; anteriorly, the hip joint, the pectineus, and the external pudic vein.

Blood-supply.—Deep femoral and obturator arteries.

Nerve-supply.—Obturator nerve.

3. =Obturator internus= (Fig. 451).—This arises by two heads within the pelvic cavity, the tendon emerging through the lesser sciatic foramen.

Origin.—(1) The pelvic surface of the pubis and ischium around the obturator foramen; (2) the pelvic surface of the shaft of the ilium and the wing of the sacrum.

Insertion.—The trochanteric fossa.

Action.—To rotate the femur outward.

Structure.—The ischio-pubic head lies on the pelvic floor and covers the obturator foramen. It is thin and fan-shaped. The iliac head extends along the lateral wall of the pelvis, and is pennate, with a central tendon throughout. Both terminate on a flat tendon which passes outward through the lesser sciatic foramen to be inserted into the trochanteric fossa. A synovial bursa facilitates the play of the tendon over the external border of the ischium.[69]

Relations.—The pelvic surface is covered by the pelvic fascia and the peritoneum. The obturator vessels and nerve lie between the two heads, and the internal pudic vessels and nerve lie along the dorsal edge of the iliac head.

Blood-supply.—Obturator and internal pudic arteries.

MINERALS IN ROCK SECTIONS THE PRACTICAL METHODS OF IDENTIFYING MINERALS IN ROCK SECTIONS WITH THE MICROSCOPE ESPECIALLY ARRANGED FOR STUDENTS IN TECHNICAL AND SCIENTIFIC SCHOOLS

BY

LEA McILVAINE LUQUER, C.E., PH.D.

Late Assistant Professor of Mineralogy, Columbia University, New York City

FOURTH REVISED EDITION

[Illustration: [Logo]]

NEW YORK D. VAN NOSTRAND COMPANY, INC. 250 FOURTH AVENUE

Copyright, 1913 BY LEA MCILVAINE LUQUER

LANCASTER PRESS, INC LANCASTER, PA.

PREFACE TO FOURTH REVISED EDITION, 1913.

This edition is practically that of 1908, with necessary minor revisions and corrections, especially the data referring to indices of refraction and strength of double refraction. The values of the refractive indices α and γ are recorded as well as the mean values. References are also given to “The Methods of Petrographic-Microscopic Research,” by F. E. Wright, 1912, for exact (quantitative) methods of determining crystal constants.

LEA MCI. LUQUER.

DEPARTMENT OF MINERALOGY, COLUMBIA UNIVERSITY, NEW YORK, May, 1913.

PREFACE TO THIRD REVISED EDITION, 1908.

The 1908 edition is essentially the same as that of 1905; the only changes being in the nature of corrections, and the addition of a brief description of the Schrœder van der Kolk method of determining refractive indices and also an abbreviated diagram for determining triclinic feldspars in sections showing both Carlsbad and Albite twinning. The Naumann symbols for crystal forms have also been omitted.

LEA MCI. LUQUER.

DEPARTMENT OF MINERALOGY, COLUMBIA UNIVERSITY, NEW YORK, April, 1908.

PREFACE TO REVISED EDITION, 1905.

In preparing the revised edition, Chapters I. and IV. have been rewritten and enlarged and the part relating to the determination of the plagioclases has been greatly amplified. Many additions have also been made to Chapter III. and the Becke method, for the determination of the relative indices of refraction of minerals, has been given in detail.

Some new and useful tables have been introduced; as tables of refractive indices (mean) and double refraction (maximum). A diagram has also been added, showing the relation existing between strength of double refraction, interference colors and thickness of section.

Professor E. Weinschenk's admirable text-book, "Die Gesteinsbildenden Mineralien", Freiburg, 1901, has been specially referred to, and the tables of refractive indices and double refraction have been compiled from Weinschenk's new Tables.

Many new cuts have been added, among them being semi-ideal drawings, showing typical outlines of crystal sections, cleavage, optical orientation, etc. In describing the "Usual Appearance in Sections" of a mineral, it is of course only possible to mention the usual crystal form in which the mineral occurs in a rock. The crystal may be cut in any way by the plane of the section; but a general knowledge of the crystal forms will furnish an idea as to the outline, etc., that the mineral may show in the section.

DEPARTMENT OF MINERALOGY, COLUMBIA UNIVERSITY, NEW YORK, July, 1905.

PREFACE TO FIRST EDITION, 1898.

The identification of minerals in rock sections with the microscope, including as it does a knowledge of optical mineralogy, is often difficult for beginners. This may be due to the fact that most of the publications on this subject are quite elaborate in their nature and in either French or German. While detailed descriptions are very necessary, and, in fact, indispensable for advanced investigation, they are apt to prove cumbersome and confusing at first. For these reasons this text-book has been prepared by the writer, with a view of putting before the student only those facts which are absolutely necessary for the proper recognition and identification of the common minerals in rock sections. The footnotes refer the student to standard publications, in which are given details of the methods and investigations outlined in the text. An elementary knowledge of crystallography and mineralogy is almost indispensable and is here assumed.

The microscopic and optical characters of the minerals are recorded in the usual order in which they would be observed with a petrographical microscope. Nearly all the rock-forming minerals become transparent in thin sections; but when opaque, attention is called to the fact and the characters are recorded as seen with incident light. White light is assumed to be used, unless otherwise stated. The interference colors recorded in all cases are those given by very thin sections of 0.03 mm. in thickness.

The order followed for the minerals is essentially that of Rosenbusch (based on the symmetry of the crystalline form), with a few exceptions made for convenience, such as placing pyrrhotite after pyrite and zoisite after epidote. The statements regarding the occurrences of minerals in the common rock-types have been taken mainly from Les Minéraux des Roches, by Lévy and Lacroix.

The terms axes and directions of elasticity, used throughout this book, are very commonly employed in petrographical literature of the present time. These axes and directions should probably more correctly be called axes and directions of vibration or extinction. The reasons for or against the elastic condition of the "ether" are of more interest, however, to the physicist than to the petrographer.

An optical scheme is appended, with the minerals grouped according to their common optical characters.

The writer's thanks are due to Dr. A. J. Moses, Professor of Mineralogy, and to Mr. J. F. Kemp, Professor of Geology, for kind suggestions offered during the preparation of this book.

TABLE OF CONTENTS

PAGE. CONVENTIONS AND ABBREVIATIONS ix

CHAPTER I. INTRODUCTORY OPTICS FOR OPTICAL MINERALOGY. Ordinary Light.—Plane Polarized Light.—Effects Produced by Crystal Sections on Transmitted Light.—Amorphous Bodies.—Isotropic Crystals.—Anisotropic Crystals.—Double Refraction.—Uniaxial Crystals.—Biaxial Crystals.—Principal Vibration Directions.—Axial Angle.—Dispersion. 1

CHAPTER II. PETROGRAPHICAL MICROSCOPE. Reflector.—Polarizer.—Nicol Prism.—Condensing Lens.—Rotating Stage.—Objectives.—Analyzer.—Eye-pieces. 7

CHAPTER III. INVESTIGATION OF MICROSCOPIC AND OPTICAL CHARACTERS OF MINERALS. Opaque Minerals. Transparent Minerals: With transmitted light: _Form_, _Color_, _Index of Refraction and Relief_, _Becke Method_, _van der Kolk Method_, _Cleavage_, _Fracture_, _Inclusions_. With polarized transmitted light: _Pleochroism_. With crossed nicols: _Isotropic Character_, _Anisotropic Character_, _Interference Colors_, _Extinction_ and _Extinction Angles_, _Vibration Directions of Faster and Slower Rays_, _Order of Interference Color_, _Strength of Double Refraction_, _Determination of Minerals and Thickness of Section_, _Structure_. With convergent light: _Uniaxial Interference Figures_ and _Optical Character_, _Biaxial Interference Figures_ and _Optical Character_, _Determination of Axial Angle_, _Distinctions between Orthorhombic, Monoclinic and Triclinic Sections_. Resumé of Uses of Parallel and Convergent Polarized Light. 13

CHAPTER IV. MICROSCOPIC AND OPTICAL CHARACTERS OF MINERALS. Amorphous Minerals.—Isometric Minerals.—Tetragonal Minerals.—Hexagonal Minerals.—Orthorhombic Minerals.—Monoclinic Minerals.—Triclinic Minerals.—Mineral Aggregates. 51

CHAPTER V. METHODS OF PREPARING SECTIONS. Cutting and Grinding Machines.—Saws.—Cutting.—Grinding. Plates or Laps.—Cementing.—Grinding.—Mounting.—Cleaning and Finishing.—Convenient Apparatus for work. 117

CHAPTER VI. CHEMICAL AND MECHANICAL TESTS. Chemical Tests on Crystal in Section: _Carbonates_, _Gelatinizing Silica_.—Etched Figures.—Heating Section to Redness.—Methods of Isolating Crystals or Fragments for Testing: _Specific Gravity Separation_, _Electro-magnetic Separation_, _Chemical Separation_.—Micro-Chemical Reactions: _Borichy's Method_, _Behren's Method_, _Special Tests_. 129

APPENDIX. Brief Scheme of Classification into Systems by Optical Determinations.—Tables of Double Refraction (maximum) and Indices of Refraction (mean).—Diagram, showing relation between strength of double refraction, interference colors and thickness of section.—Order of Consolidation of the Constituent Minerals in Plutonic Rocks.—Optical Scheme with Special Introduction. 141

INDEX. 149

CONVENTIONS AND ABBREVIATIONS.

a = The assumed direction of the ether vibrations of the fastest ray.

b = The assumed direction of the ether vibrations of the ray with intermediate velocity.

c = The assumed direction of the ether vibrations of the slowest ray.

In some American Text-Books (by Iddings, Winchell & Phillips) a = X, b = Y and c = Z.

a′ = The assumed direction of the ether vibrations of the faster ray in the given section.[1]

c′ = The assumed direction of the ether vibrations of the slower ray in the given section.

(+) = Optical character positive.

(–) = Optical character negative.

|| = Parallel to.

($\gamma - \alpha$) = The difference between the indices of refraction of the slowest and fastest rays, respectively, transmitted by the crystal, and indicates in decimals the relative strength of the double refraction.

_n′_ = The mean index of refraction;[2] hence

= $(\alpha + \beta + \gamma)/3$ or $(\varepsilon + 2\omega)/3$.

α = Index of refraction of the fastest ray.

γ = Index of refraction of the slowest ray.

_a_, _b_ and _■_ relate to the crystallographic axes commonly represented by these letters.

2_E_ = the apparent axial angle measured in air, 2_V_ being the true angle.

_Bx_{a·}_ = The acute bisectrix.

_Bx_{c·}_ = The obtuse bisectrix.

_Ax. pl._ = The axial plane, _i. e._, the plane containing the two “optic axes.”

ELONGATION relates to the appreciable extension often shown by the crystal section. A crystal of long prismatic habit, cut about parallel to the _■_ axis, would show marked elongation; while a tabular crystal (like mica) would show elongation if cut at right angles to the tabular faces. At times, of course, no elongation is appreciable, as in the case of granular or broken crystals or where the cross-section is essentially square or octagonal. Very often the relation of the cleavage is given to the elongation and also to the directions a′ and c′, which makes it possible to test for a′ and c′ even when no marked elongation can be observed.

MINERALS IN ROCK SECTIONS.

CHAPTER I. INTRODUCTORY OPTICS FOR OPTICAL MINERALOGY.

The object of this introduction is merely to give a practical discussion of elementary optics, as applied to optical mineralogy,[3] and no elaborate discussion of this important subject will be attempted. The explanations will be made as simple as possible, and, in most cases, only the optical phenomena will be described without entering into a theoretical discussion as to the cause of these phenomena.

Light[4] may be regarded as transmitted in straight lines by vibrations of the “ether,” taking place at right angles to the direction of transmission.

Ordinary light is light with the ether vibrations in all possible directions, the path described by any particle of ether constantly changing.

Plane polarized light is simply light with the ether vibrations all _parallel_ to one plane passing through the direction of transmission.

By experiment it has been proved that there exists a very close relation between the optical properties of crystals and their other physical properties, such as form, color, transmission of heat, etc. Therefore it is often possible, by a careful optical investigation of a crystal section, to determine important crystallographic facts, even in the absence of any distinct outline.

The Effects Produced by Crystals on Transmitted Light.

Consider that a series of optical tests are made on all possible sections[5] of crystals in the six systems, and the manner in which these crystals affect transmitted light ascertained.

■Isotropic Crystals■: It will be found that all sections of _Isometric_ crystals transmit light with equal velocity in all directions; that is, the crystals are optically equivalent in all directions and, hence, can produce no double refraction.[6] In these crystals any section, however cut, will transmit all the rays of light, incident to the surface at right angles, with no change.[7] The same is true of _Amorphous_ bodies, glass, etc., unless they have been subjected to strains or peculiar conditions during cooling. A _single image_ is seen through these isotropic sections.

[Illustration:

FIG. 1.]

■Anisotropic Crystals■: It will also be found that nearly all sections (the exceptions being given later) of crystals in the remaining five systems, produce quite a different effect on transmitted light. In these crystals the velocity of transmission of light varies with the _vibration direction_ of the light rays. This property, called _double refraction_,[8] seems to result from the power of resolving a ray of ordinary light, with ether vibrations in all directions, into two rays with ether vibrations in planes at right angles to each other; the two resulting rays traversing, usually, divergent paths in passing through the section.

The mineral calcite (Iceland spar) exhibits this property to a marked degree, and in certain sections will show a _double image_, Fig. 1. That the vibration directions of the two doubly refracted rays are in planes at right angles to each other, can be easily proved

by using a nicol prism.[9] In most cases the separation of the two images is so slight as not to be perceived by the eye, and the practical method of testing a crystal section for double refraction will be given later, p. 27.

The crystals that show double refraction are further divided into two groups, _uniaxial_ and _biaxial_:

(1) ■Uniaxial■, or those in which the optical characters are symmetrical to _one_ direction, called an optic axis. This _optic axis_ is the crystallographic vertical axis, _■_; and parallel to this direction there is a single value only for the light velocity and no double refraction takes place.[10] Hence any section parallel to the base (001) being at right angles to the optic axis, acts like a section of an isotropic crystal and transmits all the perpendicularly incident rays of light with no change. In any other section double refraction takes place and it can be proved by using a nicol prism that the two rays have ether vibrations, one in the plane passing through the incident ray and the _■_ axis of the crystal, and the other in a plane at right angles thereto, hence in the basal plane. This latter ray, which has a constant velocity, is called the _ordinary ray O_; and the other ray, with velocity varying with the inclination of the section to _■_, is called the _extraordinary ray E_.[11]

The vibration directions are either parallel or symmetrical to cleavage cracks and crystal outlines. In sections parallel to the optic axis, the two doubly refracted rays have the maximum difference in velocity of transmission, and hence their vibration directions are called _principal vibration directions_[12] and the plane containing them an _optical principal section_. In these sections the refractive index of the ray vibrating parallel to _■_ (extraordinary ray) is denoted by ε, and that of the ray vibrating parallel to the basal plane (ordinary ray) by ω.[13]

To this group belong all _Tetragonal_ and _Hexagonal_ crystals.

(2) ■Biaxial■, or those in which the optical characters are no longer symmetrical to an optic axis but to three planes at right angles to each other (for monochromatic light). These crystals have, however (for light of each wave-length and for each temperature), _two_ directions parallel to which there is a single value only for the light velocity and hence no double refraction. These directions are called "_optic axes_."[14] An investigation of these biaxial crystals shows that of all the rays traversing these crystals there are three rays which advance with maximum, minimum and some intermediate velocity. The vibration directions of these three rays are called the _principal vibration directions_ and are at right angles to each other (being the intersections of the three planes above referred to). The direction of ether vibration of the fastest ray is denoted by a, of the slowest ray by c, and of the ray advancing with intermediate velocity by b.[15] Each of the three planes, containing two principal vibration directions, is called an _optical principal section_. The index of refraction of the a ray is denoted by α, of the b ray by β, and of the c ray by γ.

To this group belong all crystals in the _Orthorhombic_, _Monoclinic_ and _Triclinic_ systems.

In the _Orthorhombic_ system, the principal vibration directions are parallel to the crystallographic axes; hence all pinacoidal sections contain two of these principal vibration directions. In all sections parallel to the three crystallographic axes _■_, _■_ and _■_, the vibration directions are parallel or symmetrical to cleavage cracks, crystal edges, etc.

In the _Monoclinic_ system, one principal vibration direction is parallel to the ortho axis _■_, the other principal vibration directions are in the plane of symmetry, at right angles to _■_, but are not parallel with either the vertical axis _■_ or the clino axis _á_. In clino pinacoid (010) sections the principal vibration directions will make definite angles with crystallographic lines, such as cleavages or crystal outlines. These angles are called _extinction angles_. They will vary, in this system, with reference to the direction of the _■_ axis from a maximum on the clino pinacoid (010) to 0° on the ortho pinacoid (100), when the vibration directions of the two doubly refracted rays will be parallel and at right angles to the plane of symmetry. Hence the vibration directions are parallel or symmetrical to cleavages, edges, etc., _only_ in sections parallel to the ortho axis _■_; but in all other sections are unsymmetrical.

In the _Triclinic_ system, the principal vibration directions are not parallel to the crystallographic axes, and there is no definite relation between these directions and the crystallographic axes; hence in all possible sections there will be extinction angles.

In all biaxial crystals the two _optic axes_ are inclined to each other, making what is called the _axial angle, 2V_, the apparent angle measured in air being _2E_. The optic axes lie in the plane, called the _axial plane_, which contains the principal vibration directions a and c. The axial angles are bisected by these principal vibration directions, the direction bisecting the acute angle being called the _acute bisectrix, Bx_{a}_, and that bisecting the obtuse angle the _obtuse bisectrix, Bx_{o}_. An approximate idea of the value of the axial angle can be obtained by the use of the petrographical microscope, as described later, p. 47. The axial angle is often a convenient distinction between such minerals as muscovite and biotite.

The axial angle will vary with the temperature and with light of different wave-length or color, and this variation is called _dispersion_ of the optic axes. Dispersion of the principal vibration directions also takes place in monoclinic and triclinic crystals, but can be usually disregarded.

In closing it is very important to remember that any section of an anisotropic crystal (not at right angles to an optic axis) will always transmit two rays of light with different velocities and with vibration directions in planes at right angles to each other. Isometric crystals, of course, produce no double refraction of light.

CHAPTER II. THE PETROGRAPHICAL MICROSCOPE.[16]

The _petrographical microscope_ is essentially an ordinary microscope[17] with the following important additional equipment. It must be provided with: 1° a _polarizer_ (a piece of apparatus for giving polarized light) placed below the stage; 2° an _analyzer_ (a piece of apparatus for analyzing the rays of light after they have passed through the polarizer and transparent section) placed between the objective and the eye; 3° a _stage rotating_ about an axis which is the line of sight of the microscope. A convenient type of microscope is that made by Seibert of Wetzlar (No. 11 _a_), Fig. 2.

The reflector _a_ is usually fitted with a plane mirror on one side, and a parabolic mirror on the other. The plane mirror should be used with sunlight, and the parabolic mirror with artificial light, in order to make the rays of light as nearly parallel as possible.

The _polarizer_ is in most cases a nicol prism, set in a suitable frame _b_, and made as follows:

For the _nicol prism_ “a cleavage rhombohedron of calcite (the variety Iceland spar is universally used in consequence of its transparency) is obtained, having four large and two small rhombohedral faces opposite each other. In place of the latter planes, two new surfaces are cut, making angles of 68° (instead of 71°) with the obtuse vertical edges; these then form the terminal faces of the prism. In addition to this, the prism is cut through in the direction HH′, Fig. 3, the parts then polished and cemented together again with Canada balsam. A ray of light, _ab_, entering the prism, is divided into two rays polarized at right angles to each other. One of these, _bc_, on meeting the layer of balsam (whose refractive index is less than that of the ray _bc_), suffers total reflection, and is deflected against the blackened sides of the prism and extinguished. The other, _bd_, passes through and emerges at _e_, a completely polarized ray of light, that is, a ray with vibrations in one direction only, and that the direction of the shorter diagonal of the prism.”[18] The vertical plane through the shorter diagonal may be called the _plane_ of _vibration_[19] of the nicol.

[Illustration:

FIG. 2.]

[Illustration:

FIG. 3.]

The polarizer must be below the stage _c_, and is generally adjusted so as to have its plane of vibration parallel to the N. and S. cross-wire in the eye-piece _o_. It is important to know the direction of the plane of vibration of the polarizer or lower nicol, as we can then determine, when absorption of light occurs in a mineral, the direction in this mineral parallel to which the absorbed rays are vibrating. The polarizer slides in an outer shell or frame, and, by means of a lever _d_, can easily be raised or lowered.

A convenient test for the location of this plane of vibration of the polarizer is as follows: Make use of a section of biotite, cut at right angles to the basal plane, hence showing the basal cleavage cracks. Biotite has the property of absorbing to a marked extent the light vibrating parallel to these cleavage cracks. Rotate such a section on the stage of the microscope until the position of maximum darkness is reached and when such is the case the plane of vibration of the polarizer must be parallel to these cleavage cracks.

On the top of the nicol is placed the _condensing lens_ for getting _convergent_ light, and the adjustments are so arranged that when the nicol is up as far as it will go, the condensing lens[20] is brought almost in contact with the lower surface of the transparent section resting on the stage.

The _rotating_ circular _stage e_ is supported on a suitable frame _c_, and arranged so that its axis of rotation coincides with the line of sight of the microscope. The stage is graduated, and, by means of an index fixed to the frame, the angular rotation can always be obtained. It is also provided with two adjusting screws[21] _f_, by means of which the axis of rotation can be accurately centered.

The method of centering is as follows: Bring some prominent mark in the section exactly in coincidence with the intersection of the cross-wires in the eye-piece. Rotate the stage 180°, and correct one half the error by means of the centering screws, and the other half by moving the section on the stage. Check the result by rotating the stage 180° again, and if necessary repeat the corrections in the same way until the adjustment is satisfactory.

The _objective_[22] _g_ screws into the collar _h_, which has a slot _k_, in the upper portion, for the introduction of a sensitive color plate, a one quarter undulation mica plate or a quartz wedge.[23]

The slot _k_ is so arranged that, when the sensitive color plates are introduced, the vibration directions of these plates will make an angle of 45° with the planes of vibration of the crossed nicols, and the interference color will thus be at its maximum intensity.

A revolving _nose-piece_ is sometimes used which can be attached to the collar _h_ and arranged to carry two or three objectives, which can thus be very quickly brought into position for use. This is convenient in passing rapidly from observations with parallel light to observations with convergent light, which must be made with a high power objective. The difficulty is that recentering is generally required. The modern microscopes are provided with a clip for holding the objectives, instead of the screw-thread collar _h_.

The _analyzer_[24] or upper nicol is contained in the frame _l_, which is arranged so as to slide in and out of the tube of the microscope.

The plane of vibration of the analyzer is fixed by the instrument maker so as to be at right angles to the plane of vibration of the polarizer, hence in the Seibert microscope parallel to the E. and W. cross-wire in the eye-piece. Consequently when the frame _l_ is pushed into the tube, the analyzer is introduced in the line of sight between the objective and the observer's eye, with its plane of vibration at right angles to the plane of vibration of the polarizer; that is the nicols are crossed. When the nicols are crossed, if they are properly adjusted, no light can pass through to the eye and the field of view should be dark.[25]

The _eye-piece_[26] _o_ fits into the top of the tube, and, by means of a little projecting piece fitting into a slot in the frame, can always be adjusted so as to have its cross-wires parallel to the planes of vibration of the two nicols.[25]

Some instruments are provided with an additional slot in the tube between the analyzer and the eye-piece for the introduction of a Bertrand lens, which is used to magnify the interference figures produced by convergent light.

The first approximate focusing is made by the screw _m_, and the fine adjustment by the screw _n_.

In focusing always start with the objective very near the section, and move it away until the right focus is obtained. Never move down towards the section in obtaining the focus, as there is danger then of striking the objective against the section.

For cleaning the microscope xylol can be used, as it will not injure the lacquer. To lubricate any of the parts use a small quantity of soft tallow, good clock oil or paraffin oil.

CHAPTER III. INVESTIGATION OF MICROSCOPIC AND OPTICAL CHARACTERS OF MINERALS.

■Characters of Opaque Minerals■, observed by _reflected_ light.

The minerals which remain perfectly opaque in thin rock sections have usually metallic lustre and are very minute in size, as is the case with the iron ores.

When the metallic minerals of a rock specimen are distinctly seen with the unaided eye, it is rarely necessary to make a section for their determination, as this can more easily be done by any of the well known blowpipe methods.

Form, Lustre, Color, Cleavage, etc., are recognized in the same way as in the case of macroscopic specimens. In order to make the observations by reflected light alone, the beam of light from the reflector-mirror must be cut off by holding the hand over the mirror or by moving the mirror.

■Characters of Transparent Minerals■, observed by _transmitted_ light. The petrographical microscope for these observations is supposed to be in the condition of an ordinary microscope, both nicols being out of the field and a strong beam of light coming up through the transparent section from the reflector below.

The characters are considered in the order in which they would most naturally appear to the observer during a complete investigation with the microscope.[27]

[Illustration:

FIG. 4.—Idiomorphic augite crystals in camptonite. The section is about at right angles to the vertical axis _■_, and shows the intersecting cleavages parallel to the prism of 87° 06′. Keene Valley, N. Y.]

[Illustration:

FIG. 5.—Allotriomorphic quartz _q_, showing no “relief,” plagioclase _p_ and decomposed feldspar _o_ in granite. As seen with crossed nicols.]

(_a_) ■Form.■[28] _Crystals bounded by planes_, _i. e._, crystals that have formed when conditions were favorable for complete development. Such crystals are often called _idiomorphic_ or _automorphic_, see Fig. 4. Crystals that are large in comparison with other accompanying crystals may be called _Phenocrysts_. Of course crystals, which are not wholly contained within the rock section, will only show the outline of the bounding planes cut by this particular section. In some cases, by a careful study of the outline of several sections of the same mineral and by a measurement of the angles, it is possible to determine the common “crystallographic forms” of the mineral. Very misleading outlines may, however, be observed; as for example the triangular outline of a section of a cube, with the corner truncated. For measuring the angles have the stage accurately centered, then bring the vertex of the angle to be measured to the intersection of the cross-wires in the eye-piece. Bring one of the sides in coincidence with one of the cross-wires. Note the reading of the graduated circle and rotate the section until the other side is in coincidence with the same wire. Take the reading again and the difference will be the angle required.

Crystals without bounding planes, whose surfaces are more or less determined by those of adjacent crystals. Such crystals are frequently called _allotriomorphic_ or _xenomorphic_,[29] see Fig. 5. This allotriomorphic form must not be confounded with the worn or rounded boundaries of the component grains in clastic rocks.

[Illustration:

FIG. 6.—Corroded sanidine crystal in perlite.]

Corroded Crystals,[30] whose fretted outline is undoubtedly due to corrosive action of the magma, see Fig. 6.

Broken or Strained Crystals. In some cases what were formerly larger individuals have been broken or shattered by dynamic action into much smaller fragments, see Fig. 7, showing crushed rim of fragments surrounding feldspar “auge.” In other cases an actual bending or distortion of the crystal has taken place, and again sometimes the effect of mechanical stress is only shown by the so-called “wavy” extinction. See p. 31 and Fig. 7, showing a carlsbad twin of feldspar that has been bent and therefore shows marked “wavy” extinction.

[Illustration:

FIG. 7.—Orthoclase “auge” (Carlsbad twin), showing bending and “wavy” extinction, surrounded by crushed rim of mineral fragments. As seen with crossed nicols. “Augen-gneiss,” Bedford, N. Y.—B. 13.]

[Illustration:

FIG. 8.—Crystallites and Microlites _a_. Skeleton Forms _b_.]

Crystallites, in general those incipient forms of crystals which have not yet reached a stage of development sufficient to show double refraction, see Fig. 8, _a_. Quite a number of names are used to describe the different forms that occur.

Microlites, more or less completely defined microscopic crystals, which usually show double refraction, but cannot be always specifically determined, see Fig. 8, _a_.

Skeleton Forms, resulting from rapid cooling of the magma occur in some lavas, see Fig. 8, _b_.

(_b_) ■Color.■ It must be remembered that the colors observed are always due to transmitted light and may be called “_absorption tints_.” Minerals which in hand specimens are opaque are often colored in sections; and minerals which are commonly colored may appear colorless in sections. At times color may be given to a section simply by the presence of a great number of minute

inclusions.

[Illustration:

FIG. 9.—Olivine crystal in basalt showing “high relief” and cleavage.]

(_c_) ■Index of Refraction.■ _n_ = sin _i_/sin _r_. This can be approximately determined by the appearance of the surface and outline of a mineral, that is by its _relief_. The descriptive terms are of course relative, but in common practice minerals are said to have _medium_ refraction when the refractive index is between that of balsam (1.54) and that of calcite (1.60), _strong_ refraction when higher than 1.60 and _weak_ refraction when lower than 1.54. In the case of uniaxial and biaxial minerals the mean value of the indices of refraction is used.

A mineral which has _strong refraction_ appears to have _high relief_, _i. e._, distinct dark contours and a rough or “shagreened” surface,[31] which has bright illumination and appears to stand out above the surfaces of the surrounding minerals with weaker refraction, see Fig. 9.

A mineral with _medium refraction_ does not show any _relief_, hence has a smooth surface and no dark contours, see Fig. 5.

A mineral with _weak refraction_ may also appear to have a rough surface, but not so marked as in the case of a mineral with very strong refraction, due to the smaller contrast in indices between the mineral and balsam.

The practical way of testing for the approximate index of refraction or the _relief_ of a mineral is to make use of the lens for convergent light, which is placed on top of the lower nicol immediately below the section.

By lowering[32] the lens the character of the relief of a mineral section is made very apparent.

In order to become familiar with the way in which the “relief” or appearance of the surface indicates the strength of the refractive index, the student may use a long glass slide on which are embedded in balsam (1.54) small fragments of different minerals, for example: Sodalite (1.483), orthoclase (1.523), quartz (1.547), topaz (1.620), hornblende (1.631), augite (1.70), epidote (1.751), zircon (1.95) and rutile (2.712).

Determinations of refractive indices in sections by the methods of Chaulnes,[33] Sorby,[34] or total reflection are accompanied by many difficulties and may fail to give satisfactory results. The Becke method, however, often furnishes a convenient means of determining the _relative_ values of the refractive indices of adjoining minerals or of minerals embedded in balsam. This is of especial service when one of the minerals is known and hence its refractive index.

BECKE METHOD.[35]

Suppose two adjoining minerals, in a thin rock section, to be singly refracting and to have their plane of contact vertical, _i. e._, parallel to the optic axis of the microscope.

Let _A_ and _C_, Fig. 10, be two such sections with the plane of contact _OO′_ vertical, _A_ having a lower refractive index than _C_, and consider only the direction of the rays within the section, neglecting the refractive effect of the air, glass and balsam.

A beam of transmitted light contains besides normal rays convergent rays, which pass through the section as indicated in Fig. 10. Consider now the cone of light rays _GBI_. The rays _O′G_ on meeting the plane of contact _OO′_ will be somewhat concentrated and deflected by the higher refractive index of _C_ and will continue as the cone _EF_. Some rays as _O′H_ will, on meeting the contact plane, be totally reflected and will continue as the cone _OE_, while the rest of the rays _HI_ will be dispersed and deflected by the weaker refractive index of _A_, continuing as the cone _OD_. Hence, more light rays will emerge on the side of the contact plane where the substance of higher refractive index lies, and there will be a concentration of illumination on this side producing the so-called “bright line.”

[Illustration:

FIG. 10.]

In practically making the test with a petrographical microscope remove the polarizer, analyzer and condensing lens,[36] and introduce below the section a small light-stop, to reduce in size the cone of incident light.[37] The adapter, holding this light-stop, should be adjustable so that the stop can be lowered sufficiently to produce the best results. The smaller the contrast between the

indices of refraction the smaller the incident cone of light should be, as best results are obtained when this cone is little larger than twice _O′H_, Fig. 10, all the _O′H_ rays being then totally reflected. The more of the _HI_ rays that pass through, the brighter will be the _OD_ cone and the less sharp the contrast in illumination. A high power objective[38] should be used, as those with small aperture and great focal length do not give good results. Focus on the dividing plane and adjust until equal illumination is observed on both sides and the trace of the plane resembles a fine thread, the focal plane being at _MN_. Then _raise_ the _objective_ slightly, thus moving the focal plane to _ST_, when a _bright line_ or band will appear on the side of the _stronger refracting_ substance, the width of the line depending on the contrast between _n_ and _n′_, becoming narrower as _n_ and _n′_ approach each other in value. On raising the objective still further the line broadens and finally disappears. If the objective is lowered instead of raised the reverse phenomenon will take place, the bright line appearing on the side of the weaker refracting substance.[39] When the indices are nearly the same a bright line will appear on both sides and it is important then to make the cone of incident light as small as possible and to select the _brighter_ line.

With doubly refracting minerals, each set of doubly refracted rays would suffer total reflection under somewhat different conditions and there would be no one point _B_ (as in isotropic minerals) where no bright lines would appear. However, if the cone of incident light is small enough in diameter, the test will be practically obtained as described. The Becke test can often be made with a medium power objective[40] without removing the polarizer and condensing lens, provided the condensing lens be lowered sufficiently. It may also prove convenient to turn the reflector a little sideways.

The thinner the section the more distinct will be the phenomenon. The contact plane must be clear and not coated with opaque decomposition products.

When the plane of contact _OO′_ deviates considerably from parallelism with the optic axis of the microscope a disturbance of the phenomenon may be expected and no satisfactory results be obtained. In general under these conditions the “bright line,” both on raising and lowering the objective, will remain on the side of the overlapping substance, without regard to the relative values of the indices.

The refractive index of the cementing material should not be very much lower than that of either of the thin sections, as the result would then be to disperse the emerging rays too much and dim the effect. In the case of distinguishing between minerals of high refractive power, such as augite and garnet, methyliodide is recommended instead of balsam.

In the case of doubly refracting crystals, the lower nicol (polarizer) must be retained, if it is desired to obtain the relative refractive index of one of the two rays, either with respect to the balsam or to a ray in an adjoining crystal with a parallel vibration direction. For determining vibration directions of rays and the faster and slower rays in two adjoining sections see later, pp. 31 and 33.

The method of _Schrœder van der Kolk_[41] can also be employed for the same purpose as the Becke test. The ordinary objective (Seibert No. II) is used, and the method essentially consists of darkening a portion of the field by means of the finger or a plate inserted below the polarizer. The condenser lens must be lowered beyond the sharp focus of the edge of the shadow (on raising the condenser the following phenomena are _reversed_). As the shadow approaches the contact between two minerals a bright line will appear on the edge of the “far” mineral, if its refractive index is the higher, and a dark line on this same edge if its index is lower than that of the “near” mineral. The indices of the two rays in doubly refracting minerals must be determined by the aid of the polarizer.

[Illustration:

FIG. 11.—Biotite, showing perfect cleavage, in rhyolite.]

(_d_) ■Cleavage■,[42] which appears as more or less distinct and regular lines or cracks, see Figs. 11 and 12. These cleavage cracks may be parallel or intersect, depending on the position of the section relative to the cleavage planes of the crystal.

[Illustration:

FIG. 12.—Augite _a_, showing good cleavage, and plagioclase _p_ in diabase. The plagioclase shows “polysynthetic” twinning between crossed nicols.]

[Illustration:

FIG. 13.—Garnet in mica schist, showing fracture. Franconia, N. Y.]

Cleavage is sometimes best observed by slightly lowering the condensing lens under the section.

When sections show intersecting cleavage cracks it is often possible to recognize the mineral by its known cleavage angle, as in the case of amphibole and pyroxene.

(_e_) ■Fracture■, which appears as irregular and non-parallel cracks, see Fig. 13.

[Illustration:

FIG. 14.—Apatite in feldspar _a_. Garnets in quartz, Branchville, Ct., _b_. Liquid inclusions of CO_{2}, some showing gas bubbles, in quartz _c_.]

[Illustration:

FIG. 15.—Enstatite showing “Schiller” Structure.]

(_f_) ■Inclusions■, which may be _solid_ (either distinct crystals or glass), _fluid_ or _gas_, see Fig. 14. These inclusions are distinguished by the fact that the solid inclusions generally have sharp contours, the fluid inclusions distinct dark borders, and the gas inclusions broad dark borders more distinctly marked than those of the fluid inclusions. The fluid inclusions often contain a bubble of gas. The inclusions may have a definite or indefinite position in the crystal in which they occur, and can sometimes be more distinctly seen by using convergent light or a “spot” lens.

(_g_) ■Schiller Structure.■ “Is that in which cavities of definite form and orientation (‘negative crystals’) are developed along certain planes and filled or partially filled by material dissolved out of the enclosing crystal,”[43] see Fig. 15.

Characters Observed by Polarized Light.

The polarized light is obtained by passing the beam of light from the reflector through the polarizer or lower nicol,[44] which must be in place below the stage of the microscope. White light is supposed to be used.

■Pleochroism■, that property which all anisotropic minerals have, to a greater or less extent, of absorbing certain colored rays in certain directions, thereby showing different colors in different directions by transmitted light. Uniaxial minerals are dichroic showing two differences in color, produced by the rays which vibrate parallel to the direction of the vertical axis _■_ and the plane of the basal axes. Biaxial crystals are trichroic showing theoretically three differences of color produced by rays with vibration directions corresponding very nearly to those of the three principal vibration directions.[45] Any given section of a biaxial crystal will, of course, appear only dichroic.

The practical way of testing for _pleochroism_ is as follows: Revolve the stage, carrying the section, when a change in the color of the mineral will be noticed, if it is pleochroic. This pleochroism may appear as an actual change in color or simply as a change in the shade of the same color. At times it may be so weak as hardly to be noticed, when it is best to make the test with the condensing lens in position immediately under the section, or by rotating the lower nicol instead of revolving the stage. The color of the light, vibrating parallel to certain definite crystallographic directions in minerals, is often very characteristic.

In some cases there may be such strong _absorption_ of one of the rays, that, when the vibration direction of this ray is over the plane of vibration of the polarizer, practically no light is transmitted and the section appears dark. Strong absorption is characteristic of certain minerals, such as biotite, amphibole, tourmaline and allanite and takes place parallel to definite directions in these minerals.

Pleochroism may often be noticed with ordinary light in the case of hand specimens.

Characters Observed with both Polarizer and Analyzer[46] in Position, that is with “Crossed Nicols.”

When the nicols are accurately crossed, the field should be quite dark, and if this is not the case the adjustments must be looked to. The condensing lens should be removed for these tests as they are to be made with parallel light, but as a matter of convenience instead of removing the condensing lens, the polarizer with the lens on top may be lowered, when the results will be about the same as with parallel light. White light is supposed to be used.

■Isotropic Character.■ Sections of isotropic crystals are perfectly dark and remain so during a complete rotation of the stage through 360°. The explanation is very simple. Light being transmitted by an isotropic crystal in all directions without double

refraction; it follows that the light from the polarizer, after having passed through the section, comes to the analyzer still vibrating in the plane of vibration of the polarizer. Hence it is entirely cut out by the analyzer.

Amorphous transparent substances act in the same way and remain dark during complete rotation of the stage.

Optical anomalies, _i. e._, double refraction, may occur in isometric crystals and in amorphous substances that have been subjected to strains.

■Anisotropic Character.■ Sections of anisotropic crystals, having the property of _double refraction_, produce in general some _interference_ or _polarization color_, except as mentioned later. The popular explanation is as follows:

[Illustration:

FIG. 16.]

In Fig. 16, let PP′ be the plane of vibration of the polarizer, and A′A the plane of vibration of the analyzer. All the light, after it has passed through the polarizer, is vibrating parallel to PP′ when it reaches the lower side of the transparent crystal, _cdef_, on the stage of the microscope. In this transparent section let _ob_ and _oa_ be the two _directions_ of _vibration_, _i. e._, the only two directions parallel to which rays of light can vibrate in passing through the section.

Let _om_ represent the amplitude of vibration of a ray from the polarizer. When this ray reaches the section it cannot get through it vibrating in the direction _om_, but is doubly refracted and of the two resulting rays, one gets through vibrating in the direction _ob_ and the other vibrating in the direction _oa_. From _m_ draw perpendiculars to _ob_ and _oa_. Then according to the law of the parallelogram of forces _ob_ will represent the amplitude of vibration of the ray passing through the crystal vibrating in the direction _ob_, and _oa_ will represent the amplitude of vibration of the ray passing through the crystal vibrating in the direction _oa_. We will thus have two rays passing through the crystal, polarized at right angles to each other.

[Illustration:

FIG. 17.]

Consider now the general question of the transmission of the doubly refracted rays through a plate. Whatever the angle of the parallel incident rays, each ray as AB, Fig. 17, is resolved, as just described, into two rays BC and BD, polarized at right angles to each other and following (usually) different paths in the plate. On emergence these follow parallel paths. Among the incident rays there are rays EG and FH, such that one component of FH will emerge at D with one of the components of AB, and one component of AB and one component of EG will emerge at C. Hence from every point of the upper surface of the plate there will emerge two rays and these rays will have travelled through different paths in the plate with different velocities and will have their vibrations at right angles to each other.

When these doubly refracted rays come to the analyzer, whose plane of vibration is A′A, they cannot get through vibrating in their present directions, but components of these rays, such as _ot_ and _os_, can get through vibrating parallel to the plane A′A.

Hence we have two series of rays coming to the eye, polarized in the same plane, but one set slightly in advance of the other. These rays will “interfere” and produce some _interference_ or _polarization_ color.[47] In using white light whenever one of two light rays of the same color has suffered a “retardation” of just one wave-length (or even multiple thereof) the color will be extinguished; and when the “retardation” is one half wave-length (or even multiple thereof) the color will be intensified. Therefore, some tints will be extinguished and others intensified, the combination resulting in the production of some definite interference color. Of course in the case of monochromatic light the thickness of the section may be such that “destructive interference” takes place producing no color (darkness).

Now suppose the stage to be rotated until the section _cdef_ takes the position _c′d′e′f′_. The section will be found to be dark and no interference color will be seen. This is due to the fact that the directions of vibration in the section are parallel to the planes of vibration of the crossed nicols, consequently the light passes through the section still vibrating parallel to the plane PP′ of the polarizer and is all cut out by the analyzer. Darkness will occur every 90° and therefore four times during a complete rotation of the stage. The interference color is also observed to vary in intensity, but not in color, and to be at its maximum 45° from the positions of darkness.

Sections of uniaxial crystals at right angles to the optic axis act like isotropic substances and remain dark during a complete rotation of the stage. In the biaxial crystals, a section at right angles to an “optic axis” shows uniform illumination[48] which does not change as the stage is rotated.

The only way to find out whether sections that remain dark are isotropic, or uniaxial at right angles to an optic axis, is to test them with convergent light as described later, see p. 40.

■Interference Colors.■ The interference color shown by any mineral section depends on three factors: 1° the strength of the double refraction (_γ_ − _α_ = the difference between the refractive indices of the slowest and fastest rays); 2° the position of the section in the crystal; 3° the thickness of the crystal section.

To eliminate, so far as possible, the variation due to the optical orientation of the section, care must always be taken to obtain the maximum interference color given by the different sections of the same mineral in the rock section. Sections giving the maximum color are those parallel to the _■_ axis in uniaxial minerals and those parallel to the axial plane in biaxial minerals.[49] Hence such sections in convergent light never show the emergence of an optic axis or a bisectrix; and furthermore, other clues, such as crystal outlines, cleavage, pleochroism, etc., may help to indicate the favorable section.

The influence of the thickness of the section is also important and must be considered. The interference color will rise in the scale (be higher in order) as the section becomes thicker. Methods of obtaining the thickness of a section are given on pp. 35 and 36. When reference is made to definite interference colors the mineral section is supposed to have a thickness of 0.03 mm. and to be such as to give the maximum color; and all mineral sections in a rock section are considered to have a uniform thickness.

With these precautions in mind the _interference colors_ indicate the _strength_ of the _double refraction_ as follows:[50] The colors of minerals with very weak double refraction vary from a bluish-gray to a grayish-white. As the strength of the double refraction increases the colors become the very intense bright tints of the spectrum, yellow, red, blue, green, etc., called the first and second order colors. As the strength of the double refraction still increases the colors pass through the tints of the spectrum in sequence (called orders), becoming paler until finally, when the double refraction is very strong, the colors become the neutral, almost colorless tints of the higher orders. The eye must be trained to appreciate the colors of different orders, and the student is advised to practice with mineral sections, of known strength of double refraction, and compare the resulting interference colors with a color chart,[51] or use the interference color diagram at the end of the book. A convenient test can be made with a one fourth undulation mica plate to distinguish between the white of the 1° order and the practically white very high order tint. Introduce the mica plate in the slot _k_, Fig. 2, and the effect will be to produce a marked change in the color of the 1° order, while no change will be observed in the high order color.

The exact order of the color can be determined by the use of a quartz wedge, as described on p. 35.

Abnormal Interference Colors[52] may be brought about in several ways. In white light strong absorption of part of the light components may not only alter the color of the mineral but also modify the interference color. The double refraction may be nearly zero for light of a particular color so that the mineral is isotropic for that color, resulting in a change in the interference color, as for example the indigo of melilite, which is nearly isotropic for yellow light. In biaxial minerals the axial angle may be zero for light of a particular color, resulting also in a modification of the interference color, as the blue in penninite in sections ■ _Bx_{a}_. When the bisectrices are much dispersed there will be no position of darkness between crossed nicols in white light.

■Extinction and Extinction Angles.■ When the section, see Fig. 16, is in such a position that its directions of vibration are parallel to the planes of vibration of the nicols, no light can pass through the analyzer, and the section is dark. Hence the light is extinguished and this phenomenon is called _extinction_.

Extinction is said to be _parallel_ or _symmetrical_ when the directions of vibration are parallel to any crystallographic lines or directions, or bisect the angles between these lines. The crystallographic lines or directions may be either cleavages or the similar boundaries of idiomorphic crystals.

This kind of _extinction_ is shown by all sections of tetragonal and hexagonal crystals, by all sections parallel to the crystal axes in orthorhombic crystals and also by the sections parallel to the ■ axis in monoclinic crystals.

When the _extinction_ is not symmetrical it is called _oblique_, and is shown by all sections of monoclinic crystals (except those parallel to the ■ axis) and triclinic crystals.

Extinction which does not take place over the whole of the section of a single crystal at the same moment, but passes over the section like a dark wave or shadow, is said to be “_wavy_”; and indicates that the crystal has been subjected to mechanical forces producing a change in the position of the directions of vibration in different parts of the crystal, see Fig. 7.

The angle between a direction of vibration in the section and some known crystallographic direction (as a cleavage or crystal outline) is called an _extinction angle_, and is measured in the following way: Find the positions of the directions of vibration in the section, which must be parallel to the cross-wires when extinction takes place. Note the reading on the graduated circle of the stage, then remove the upper nicol, in order to get a more distinct view of the field, and rotate the stage until you bring some known crystallographic line into parallel position with the cross-wire selected as a reference line. Take the reading of the graduated circle again, and the difference between these two readings will be the _extinction angle_.

It can readily be seen that depending on which way the section is rotated, either a small or a large extinction angle will be obtained, the two angles being complements of each other. The extinction angle generally recorded is that between the nearest direction of vibration and the vertical axis _■_.

In monoclinic minerals the maximum value of the extinction angle (the angle of real value in distinguishing the mineral) can only be obtained from a section parallel to the clino pinacoid (010); but in practice sufficiently accurate results can generally be obtained by measuring the extinction angles of all sections of the same mineral, which seem to be about parallel to the vertical axis _■_, and then taking the maximum value obtained. Amphibole and pyroxene can easily be distinguished in this way.

Extinction is generally tested for by revolving the stage, carrying the section, until darkness is observed. The principal difficulty, however, is caused by the eye failing to appreciate the position of maximum darkness. Hence it is better to revolve the stage until the section just becomes dark (or fades out) and then revolve further until the section just begins to lighten up again. The mean of the readings, in these two positions, will be the one to use.

A gypsum test-plate, so prepared as to give some definite interference color, as red of the 1° order, may be introduced between the two nicols, and the section revolved until this color is exactly matched. This perfect matching of color is only possible when the directions of vibration of the section are exactly parallel to the planes of vibration of the nicols, as otherwise some interference color would be produced by the section and the true color of the test-plate would not appear. The most favorable condition is when the section is colorless and only covers a part of the field of view, as then the rest of the field shows the color of the test-plate and the exact matching of color is an easy matter. This method of testing can be employed to recognize the very weak double refraction of some minerals, whose interference colors are such dark grays as not to be noticed without this test. After the test-plate has been introduced, some slight variation in the color will be observed when the stage carrying the doubly refracting section is rotated. There are other methods[53] for locating these directions of vibration. They depend generally on substituting changes of color for degrees of darkness or on changes in interference figures, and consist in the use of color test-plates or Klein’s quartz-plate, or of special oculars prepared by Bertrand, Calderon, etc.

METHOD OF TESTING FOR THE VIBRATION DIRECTIONS OF THE FASTER AND SLOWER RAYS, _A′_ AND _C′_, IN A MINERAL SECTION.

A mica or gypsum plate can be used to make this test, the directions of vibration of the faster and slower rays on these plates being known and marked.[54]

The crystal section to be tested is placed on the rotating stage, between crossed nicols, and turned to the position of extinction, when these directions of vibration will be parallel to the cross-wires in the eye-piece. The section is then turned 45°, when the interference color will be at its maximum, and these directions of vibration will make angles of 45° with the planes of vibration of the nicols and the cross-wires in the eye-piece.

Now introduce[55] the test-plate, between the section and the analyzer, so that its known directions of vibration also make angles of 45° with the cross-wires in the eye-piece.

When the test-plate is introduced a new interference color will be noticed which is either higher or lower in the color scale[56] than the original interference color of the mineral section. When the known directions of vibration of the test-plate are superposed over corresponding directions in the mineral section, the effect is to thicken the section and the interference color rises in the scale.

When the directions of vibration of the test-plate are superposed over directions of vibration in the mineral section which are not corresponding, the effect is to thin the section and the interference color sinks in the scale.

For minerals which have very strong double refraction, as zircons, so that the interference colors are of the higher orders, it is advisable to use the method of testing with a quartz wedge.[57]

If a wedge is inserted between crossed nicols and its _c_ direction inclined at 45° to the planes of vibration of the nicols, then successive interference colors will be seen commencing with the gray of the first order and passing through the colors as shown by a color chart. If now the crystal section lies with its vibration directions also in the diagonal position, the color of any portion of the quartz wedge will be changed where it covers the section, the new color being that of a thicker part of the wedge if the _c_ direction in the section lies under the _c_ direction of the wedge. Also where the wedge overlaps the section the displacement of the color fringes in the section will be towards the thin edge of the wedge. On the other hand the new color will be that of a thinner part of the wedge when the _a_ direction in the section lies under the _c_ direction of the wedge. In this case the displacement of the color fringes will be towards the thick part of the wedge.

This method is very convenient when the crystal section has in any place sloping edges, showing prismatic color fringes. The movement of these fringes (as previously described) is towards the thin edge of the wedge when the vibration directions correspond and away from this edge when they do not correspond.

If the wedge when inserted finally “compensates” the color of the crystal section (_i. e._, practically produces an absence of color, darkness), then the a in this section must lie under the c in the wedge, as the effect of the wedge has been to continually thin the section.

DETERMINATION OF ORDER OF INTERFERENCE COLOR.

This can be determined by use of a quartz wedge or a v. Federow mica wedge.[58] Have the vibration directions of the given section in the diagonal position, then gradually insert the wedge between the crossed nicols so that the corresponding vibration directions in the section and wedge are crossed, that is so that the colors are run down until finally dark gray or black is obtained. Count the number of times the original interference color reappears, if _n_ times, then the color is a red, blue, green, etc., of _n_ + 1 order.[59]

It is often easier to insert the wedge until compensation of the color is obtained; then as the wedge is pulled out the direct count of the recurrence of the original color will give the order of that color.

METHOD OF MEASURING THE STRENGTH OF THE DOUBLE REFRACTION BY VON FEDEROW MICA WEDGE.[60]

“The wedge[61] consists of fifteen superposed quarter undulation mica plates, each about two mm. shorter than the one beneath it and with their directions of vibration parallel. The series is mounted on a strip of glass and covered with a cover-glass.

The wave-length of a middle color may be taken as 560 μμ (millionths of a millimeter); hence each quarter undulation mica plate may be considered to possess a phase difference or retardation of 140 μμ. If, then, between the polarizer and analyzer we insert the mica wedge, so that its direction of vibration of the slower ray, _c_, is at right angles to that of the mineral under examination, we subtract from the phase difference of the mineral an amount equal to _n_ times 140 μμ, in which _n_ represents the number of superposed mica plates in the field. When the mineral appears dark the value evidently corresponds closely to the phase difference of the mineral.[62]

From the expression $\Delta = _eX_$, in which Δ is the phase difference or retardation, _X_ the double refraction, and _e_ the thickness in millionths of millimeters, the thickness can be deduced when the double refraction is known or _vice versa_. If a mineral of known double refraction can be found in the section near the mineral under investigation,[63] the double refraction of the latter can be deduced by measuring the phase difference of the known mineral, whence e results, and this substituted in the above formula yields _X_.”

METHOD OF DETERMINING MINERALS AND THICKNESS OF SECTION, BY USE OF TABLE OF DOUBLE REFRACTION (MAXIMUM) AND DIAGRAM.[64]

Select some easily recognized mineral in the rock section and note the maximum interference color given by any of its sections.[65] The strength of the double refraction of this mineral being known, look up on the diagram the diagonal line corresponding to this

double refraction and follow along this line toward the left hand lower corner until the observed interference color is reached, when the horizontal line will indicate the thickness of the section. The thickness is given in hundredths of millimeters. Then in the case of the unknown mineral pick out the section giving the highest interference color and carry along the same horizontal line until this new color is located,[66] then pass up to the right along the diagonal line to the numbers indicating the strength of the double refraction of the unknown mineral. Turn to the table where the minerals will be found having about this strength of double refraction.

Example: In a section of granite (biotite-granite) a grain of quartz was selected, which gave the brightest color. This color was a bright yellowish white and the known double refraction of quartz is 0.009. Following down on this diagonal line until the interference color was reached it was seen that the thickness of the section was about 0.03 mm. (a very thin section). The section of the undetermined mineral, giving the highest order color, showed a bright 2° order purple-blue. Passing along the 0.03 horizontal line until this color was reached and then up along the diagonal line, it was seen that the double refraction of this mineral must be about 0.04. The table gives muscovite and ægerite as having about this double refraction. The mineral was proved to be muscovite by its absence of color and relief and by the characteristic cleavage and parallel extinction.

[Illustration:

FIG. 18.—Sanidine crystal _f_, showing Carlsbad twin (which, as it consists of two parts only, may be called _simple_), and quartz _q_ in rhyolite. Crossed nicols.]

Structure:

(_a_) _Twinning_, generally noticed by the parts of the twin not extinguishing at the same time. It may also be observed, without crossed nicols, just as in the case of macroscopic minerals.

Twinning may be described as: _simple_, Fig. 18; _polysynthetic_, due to repeated twinning after the same law, Fig. 12; and _crossed or “gridiron,”_ due to repeated twinning after two laws, Fig. 19.

[Illustration:

FIG. 19.—Microcline, showing crossed or “gridiron” twinning. Crossed nicols.]

(_b_) _Zonal_ structure, often only made visible by the zones extinguishing at different times. It may, however, be noticed by the zones being of slightly different color, or by the zonal distribution of inclusions. In the case of the feldspars the zonal structure may be caused either by the crystal being formed of zones of different chemical composition (the successive zones in the plagioclases growing more acid towards the exterior), or by ultra-microscopic twinning,[67] Fig. 20.

[Illustration:

FIG. 20.—Zonal feldspar (Carlsbad twin) in trachyte. Crossed nicols.]

(_c_) _Aggregate_ structure, being a confused mass of separate little crystals, scales or grains all extinguishing at different times, Fig. 21.

[Illustration:

FIG. 21.—Sphærulites in felsite. Ground mass shows aggregate structure. Crossed nicols.]

(_d_) _Sphærulitic_ structure, produced by the aggregation, in a radiate form, of crystals or crystallites. It is generally easily perceived by the dark cross, resulting from the extinguishing of the light in those crystals whose directions of vibration are parallel to the planes of vibration of the nicols. When the stage is revolved the arms of the cross do not rotate, Fig. 21.

[Illustration:

FIG. 22.—Olivine decomposed to serpentine. The pseudomorphism has been almost complete, only small portions of the original olivine remaining. The outline of the parent crystal can be quite distinctly seen. Crossed nicols.]

(_e_) _Pseudomorphic_ structure, which may be partial or complete and is noticed by the changed portions producing different optical effects from those of the original mineral. Sometimes, although the pseudomorphism has been almost complete, the form of the original mineral or crystal may still be seen, Fig. 22.

Characters Observed by Convergent Polarized Light.

Convergent light is obtained by passing the rays of polarized light through a strong condensing lens, which generally fits like a cap over the top of the polarizer. By means of a suitable adjustment the condensing lens can be brought very close to the lower surface of the section on the stage. The lens thus sends a cone of light through the section, and used in connection with _crossed nicols_ a series of optical phenomena, called _interference figures_,[68] are produced.

Each direction in which rays are sent is traversed by a minute bundle of parallel rays and these rays extinguish and produce interference colors as already described for parallel light. Hence each direction yields a spot or picture in the field of view and from all these spots combined there results an “interference figure” or picture, depending upon the structure of the section for all the directions traversed by the rays.

A very high power objective[69] must be used, and when the eye-piece is removed, a small image of the interference figure will be seen. In some microscopes an arrangement is made for getting a magnified image of the interference figure, by retaining the eye-piece and using an additional Bertrand lens.

In order to get good results care must be taken to have strong illumination and the condensing lens close up under the section. The tests are best made with monochromatic light, but with white light the effects are substantially the same, the only difference being that the rings and curves are variously colored instead of being simply light and dark.

Isotropic substances show no _interference figures_.

Uniaxial Interference Figures.

(_a_) Sections perpendicular to the optic or vertical axis _■_ show a dark cross, with or without colored rings, Figs. 23 and 24. The figure is symmetrical to the center, as the optical behavior of uniaxial crystals is symmetrical to the optic axis.

[Illustration:

FIG. 23.]

[Illustration:

FIG. 24.]

The arms of the cross are parallel to the planes of vibration of the nicols, and the figure does not move when the stage carrying the section is rotated.[70]

(_b_) Sections oblique to the optic axis show a portion of a dark cross, with or without colored rings, Fig. 25. The centre of the cross is not in the axis of rotation, and as the stage bearing the section is revolved, the centre of the cross describes a circle, the arms always maintaining parallel positions.

If the section is still more oblique to the optic axis the centre of the interference cross may be outside the field of view, and only portions of the dark arms will be seen.

Sections parallel to the optic axis show a vague dark cross, which, on rotating the stage, dissolves into hyperbolic curves (suggesting biaxial figure), which very rapidly disappear in the direction of the optic axis. When the interference figure shows colors, these colors are lower in order in the quadrants containing the optic axis. Knowing thus the position of the optic axis the optical character can be obtained by the method for parallel light, p. 43.

[Illustration:

FIG. 25.]

Sections which are thick and have strong double refraction will show the cross and rings clearly and sharply defined, there being quite a number of rings crowded close together. Sections which are very thin and have weak double refraction show only a broad dark cross and no rings. The interference figures will vary between these extremes, depending on the thickness of the section and the strength of the double refraction.

To obtain the most characteristic figures, observations must be made on sections about perpendicular to the optic axis, that is sections which remain dark or nearly dark during complete rotation between crossed nicols in parallel light.

■Optical Character, Positive or Negative.■ After having obtained an uniaxial interference figure, test it by means of a ¼ undulation mica plate. This plate must be introduced between the objective[71] and the analyzer in such a way that its vibration direction c, marked on the plate, makes an angle of 45° with the planes of vibration of the nicols.

When this is done the interference figure changes, or may more or less disappear, two dark spots or blotches being brought prominently into view. If rings are still seen it will be noticed that they have expanded in the quadrants occupied by the dark spots, and have contracted in the remaining quadrants. This movement of the rings may make it possible to determine the optical character of a section, which is so oblique to the optic axis that the dark spots are not seen after the introduction of the mica plate.

[Illustration:

FIG. 26.]

[Illustration:

FIG. 27.]

If the optical character is _positive_ the line joining these dark spots is perpendicular to the direction c of the mica plate, see Fig. 26.

If _negative_ the line joining the dark spots coincides with the direction c of the mica plate, see Fig. 27.

The (+) and (–) character is easily determined by remembering that the line, joining the dark spots, makes the + and – sign respectively with the direction c of the mica plate. The direction c of the mica plate (represented in the figures by an arrow) is of course not seen, but its position must be borne in mind when making this test. This test can be made with either monochromatic or white light.

If the mica plate does not give satisfactory results, which will be the case when the double refraction of the crystal to be tested is very weak or when the section is very thin, use a selenite plate, cut the proper thickness to give the red color of the first order.

This plate must be introduced with its vibration direction a (previously determined) making an angle of 45° with the planes of vibration of the nicols. Instead of the dark spots being seen there will appear two blue and two red quadrants. The diagonally opposite quadrants being of the same color.

In determining the (+) and (–) character consider the blue quadrants as the equivalent of the dark spots in the preceding case. This test must be made with white light.[72]

Biaxial Interference Figures.

[Illustration:

FIG. 28.]

[Illustration:

FIG. 29.]

(_a_) Sections perpendicular to an optic axis exhibit the interference figures shown in Figs. 28 and 29, the curves being nearly circular and a straight black bar bisecting these curves, whenever the trace of the plane of the optic axes coincides with the vibration direction of either nicol. As the stage, carrying the section, is rotated the bar changes into one arm of a hyperbola and back again into a bar. This arm or bar will rotate in the opposite direction to the motion of the stage.

As previously stated sections of biaxial crystals, perpendicular to an optic axis, do not remain dark during rotation of the stage between crossed nicols in parallel light. On the contrary these sections remain uniformly illuminated.[73]

(_b_) Sections perpendicular to the acute bisectrix (see p. 5), exhibit interference figures like those shown in Figs. 30 and 31.

[Illustration:

FIG. 30.]

[Illustration:

FIG. 31.]

Fig. 30 shows the appearance of the interference figure when the plane of the optic axes is parallel to the plane of vibration of either nicol, and Fig. 31 shows the appearance when this plane is inclined 45° to the planes of vibration of the nicols.

As the stage, carrying the section, is rotated the dark cross seems to dissolve into two branches of a hyperbola, which again unite to form a cross.

In sections perpendicular to a bisectrix, with a large axial angle, the figure will appear, during a rotation of 90° (in the direction of the hands of a watch), as in Fig. 32, top row. When the section is somewhat oblique to an “optic axis,” the figure appears as in middle row; and when still more oblique, as in bottom row.

The black centres[74] of the small ellipses and the black hyperbolic curves mark the points of emergence of the optic axes, and therefore indicate approximately the size of the _axial angle_, 2_E_.

Sections in other positions, relative to the optic axes, give interference figures less definite in appearance than those just described; and the same conditions affect the appearance of all figures as in the case of uniaxial crystals. Very thin sections, of weak double refraction, may only show indistinct dark crosses or hyperbolic curves, without any ellipses.

The section perpendicular to the acute bisectrix, which gives the most characteristic interference figure, cannot generally be recognized except by an examination in convergent light. It is never, however, the section giving the maximum interference color. The interference colors in different sections, normal to the optical elements, grade downward in the following order: (1) optic normal, (2) obtuse bisectrix, (3) acute bisectrix, (4) optic axis. Sometimes cleavage may furnish a clue as to the best section to test as in Topaz and Mica, where the acute bisectrix is normal to the cleavage.

[Illustration:

FIG. 32.—Biaxial Interference Figures (from Reinisch). Top row: Almost perpendicular to bisectrix, large axial angle. Middle row: Somewhat oblique to an “optic axis.” Bottom row: More oblique to an “optic axis.”]

It must be remembered that this uncertainty, in the choice of sections for testing, does not exist in uniaxial crystals; where the best sections are indicated by the fact that they remain dark or nearly so during complete rotation between crossed nicols.

The uniaxial or biaxial character of a mineral section, which only shows an indistinct bar, may be determined as follows: A bar (one arm of the cross) of a uniaxial interference figure moves in the same direction as the rotating stage, and always remains straight, while the biaxial bar rotates in the opposite direction to the stage and becomes curved.

■Optical Character, Positive or Negative.■ When the axial angle is very small, so that the interference figure approaches that of a uniaxial crystal, the methods used for testing uniaxial figures are employed.

When, however, the axial angle is large, the following method can be used:

After having obtained an interference figure, from a section as nearly at right angles to the acute bisectrix[75] as possible, the stage is rotated until the plane of the optic axes (the trace of which on the plane of the section is the line joining the points of emergence of the two optic axes) makes an angle of 45° with the planes of vibration of the crossed nicols or the cross-wires in the eye-piece.

A quartz wedge[76] is now pushed in between the mineral section and the analyzer,[77] so that its axis _■_ = c (previously determined and marked on the wedge) is either at right angles or parallel to the plane of the optic axes of the mineral section.

The optical character of the mineral is _positive_ when the ellipses, surrounding the points of emergence of the two optic axes on the convex sides of the hyperbola, appear to expand or open out towards the centre when the quartz wedge is pushed in with its axis parallel to the plane of the optic axes.

The optical character is _negative_ when the ellipses appear to expand or open out when the wedge is pushed in with its axis at right angles to the plane of the optic axes.

As the ellipses expand they move from the points of emergence of the optic axes towards the centre of the interference figure, and finally open into lemniscates which move outward from the plane of the optic axes.

Even when the section is very thin and the double refraction very weak, only the black hyperbolas without ellipses being seen, the test can be made; and colored ellipses will appear, after the pushing in of the quartz wedge, which will act in the same way as the ellipses of the interference figure.

In a section at right angles to the _obtuse bisectric_ these results are all reversed.

When the section is perpendicular to one optic axis, rotate the section until the plane of its optic axes is 45° to the planes of vibration of the nicols. The interference figure will now have the appearance as shown in Fig. 29, the hyperbola being convex towards the acute bisectrix. Insert the ¼ undulation mica plate, so that its direction c is parallel to the plane of the optic axes. If the optical character is positive the hyperbola will move towards the acute bisectrix and if negative away from it. When the gypsum plate is used the blue color will appear on the convex side for (+) and on the concave side for (–) minerals.

■Determination of the Axial Angle.■[78] This can be approximately determined with a petrographical microscope, if equipped with a micrometer eye-piece. Have the axial plane of the crystal section in the diagonal position, Fig. 31; and measure the distance _d_ from the centre to either hyperbola with a micrometer (or average the distance to both). Then sin _E = d/C_, in which _C_ is a constant for the same combination of lenses and is obtained by using a crystal section (mica cleavage) of known axial angle. For example, in a mica with 2_E_ = 91° 50′ and _d_ = 41.5 divisions on the micrometer scale, _C = d_/sin _E_ = 57.78 for that special combination of lenses. The true axial angle can be obtained from the equation sin _V = d/βC_.

■Optical Distinctions between Orthorhombic, Monoclinic, and Triclinic Crystal Sections (perpendicular to acute and obtuse bisectrices).■ The interference figures are always symmetrical in shape and distribution of color to the planes and axes of symmetry of the crystal system; hence are most symmetrical in the orthorhombic, less so in the monoclinic and still less so in the triclinic system.

Orthorhombic crystals show the figures always in two of the pinacoids and in white light the color distribution will be symmetrical to the trace of the axial plane and the line through the centre at right angles to this trace and also to the central point.

Monoclinic crystals show the figures in the clino pinacoid or in sections at right angles to this. In white light the color distribution is never symmetrical to two lines, but is symmetrical either to the trace of the axial plane (_inclined dispersion_[79]), or to the line through the centre at right angles to this trace (_horizontal dispersion_), or to the central point (_crossed dispersion_).

Triclinic crystals show in white light figures with distribution of color unsymmetrical to any line or point.

In white light the “color fringes” of the hyperbola are due to the “_dispersion_”[79] of the optic axes and bisectrices. That is, for each color (for light of each wave-length) there is a particular interference figure; the overlapping of these superposed figures producing the color fringes.

When the axial angle is larger for red light than for violet, the dispersion is said to be $\rho > \nu$ and the interference figure, in the position of Fig. 31, will show the hyperbolic curves fringed with red towards the centre (inside). In general the color with the larger axial angle is nearer the centre of the field. This is due to the extinguishing of light of each color at the axial points, the resulting colors at these points being produced by white light minus the absorbed color. When the dispersion is $\nu > \rho$ the reverse distribution of color fringes will take place.

By measuring the axial angle in red and blue light, this dispersion of the optic axes can also be obtained.

RESUMÉ OF THE USES OF PARALLEL AND CONVERGENT POLARIZED LIGHT.

Parallel light is used to detect pleochroism, to distinguish between isotropic and anisotropic substances, to study interference colors, to determine the strength of the double refraction, to locate directions of vibration, to measure extinction angles, to find the directions of vibration of the faster and slower rays, to determine the relative value of the indices of refraction of the two rays, and to investigate the crystal structure in general.

Convergent light is used to distinguish between uniaxial and biaxial crystals, to determine whether a section that appears to be isotropic is really so or only perpendicular to an optic axis and to determine the optical character, grade of symmetry (system), axial

angle and dispersion.

CHAPTER IV. THE MICROSCOPIC AND OPTICAL CHARACTERS OF MINERALS.

OPAL.

ISOTROPIC. AMORPHOUS.

COMPOSITION: $SiO_{2}.nH_{2}O$, generally soluble in caustic alkalies.

■Usual Appearance in Sections■: Colorless patches, incrustations or veins, also at times with sphærulitic structure (hyalite), showing interference cross, of negative character, between crossed nicols. Often shows anomalous double refraction due to strains. The refractive index is very low (1.46) so that the surface of the opal appears rough.

REMARKS: Found as a secondary mineral in many acid volcanic rocks, rhyolite, trachyte, andesite, etc., and also in basic basalts. H., 5.5 to 6.5. Sp. gr., 2.2.

LIMONITE.

AMORPHOUS.

COMPOSITION: $Fe_{2}(OH)_{6}$, $Fe_{2}O_{3}$, frequently quite impure.

■Usual Appearance in Sections■: Brownish and opaque, in very thin sections may be translucent.

REMARKS: Limonite is essentially a decomposition product, often forming pseudomorphs after ferruginous silicates or halos about the iron ores.

PYRITE, Pyrites.

ISOMETRIC. COMPOSITION: FeS_{2}.

■Usual Appearance in Sections■: Cubes, pyritohedrons, combinations of these forms; or in irregular grains. Outline of cross-sections generally square.

Opaque, and by reflected light, bright yellow, with strong metallic lustre.

Alters very easily to the oxides of iron (rust).

REMARKS: May be present in all kinds of rocks, igneous, metamorphic and sedimentary. Not noticeably acted on by hydrochloric acid. H., 6 to 6.5. Sp. gr., 4.9 to 5.2.

PYRRHOTITE, Magnetic Pyrites.

COMPOSITION: FeS. Distinguished from pyrite by being practically always in irregular masses and not in crystals, and by bronze yellow color with reflected light. Found in basic eruptive rocks, more rarely in schists.

MAGNETITE, Magnetic Iron Ore.

ISOMETRIC.

COMPOSITION: $Fe_{3}O_{4}$, often contains Ti.

■Usual Appearance in Sections■: Grains and crystals (generally octahedra), Fig. 33 B. Skeleton crystals frequent in highly ferruginous eruptive rocks.

Twinning.—Common, according to _Spinel_ law.

[Illustration:

FIG. 33.—_A_, Zircon crystals (isolated from granite) in balsam, showing high relief. _B_, Magnetite crystals. _C_, Ilmenite, showing partial decomposition to _leucoxene_ along crystallographic directions.]

Opaque, and by reflected light, bluish-black, with strong metallic lustre.

■Distinguished from■: HEMATITE, CHROMITE, ILMENITE and GRAPHITE, by being easily separated from powdered rock by weak magnet.

REMARKS: Very widely distributed in eruptive rocks and crystalline schists. In the eruptive rocks magnetite belongs to the oldest secretions from the magma, immediately followed by chrysolite, biotite, hornblende, augite, etc.; hence often appears as inclusions in these and other minerals. Magnetite grains may form with other substances pseudomorphs after hornblende, biotite, hypersthene, etc. Such pseudomorphs appear to be caused by “resorption.” Magnetite is strongly magnetic and soluble in hydrochloric acid. H., 5.5 to 6.5. Sp. gr., 4.9 to 5.2.

CHROMITE.

ISOMETRIC.

COMPOSITION: $FeCr_{2}O_{4}$.

■Usual Appearance in Sections■: Octahedral crystals, grains and in the olivine rocks sometimes in dense aggregates. May be surrounded by green, pleochroic halo of chrome ochre.

Opaque, and by reflected light, brownish-black to black, with general absence of metallic lustre. Usually translucent and brownish on the edges (by transmitted light), with a very rough surface due to high index of refraction (_n_ = 2.1).

■Distinguished from■:

(_a_) MAGNETITE by brownish-black to black color and general absence of metallic lustre (by reflected light) and by grains being usually translucent and brownish on the edges (by transmitted light).

(_b_) SPINEL (Picotite), see under Spinel.

REMARKS: Common in crystalline rocks, rich in magnesia, and in serpentine. Chromite is not acted on by acids, is non-magnetic and gives chromium bead test. H., 5.5. Sp. gr., 4.3 to 5.6.

SPINEL.

ISOTROPIC. ISOMETRIC.

COMPOSITION: $Mg(AlO_{2})_{2}$. Pleonaste (Fe, Mg spinel), Picotite (Cr spinel).

■Usual Appearance in Sections■: Octahedral crystals and twins (after spinel law), less often in grains. Fracture cracks. Always optically normal and never decomposed in rocks. Usually colorless or dark green (pleonaste) to brown (picotite). The refractive index is high (_n_ = 1.72, spinel proper, to 2.00, chrome spinel), hence the _relief_ is marked and the surface rough.

■Distinguished from■:

(_a_) GARNET when colorless by octahedral shape of crystals (garnet forms being 110 and 211), when brown (picotite) from melanite garnet by common zonal coloration of the latter, but may require chemical tests. Furthermore spinel may have green color and is never decomposed.

(_b_) PEROVSKITE by the lower index of refraction and the absence of reaction for Ti.

(_c_) CHROMITE chemically or by density or hardness.

REMARKS: Found in gneiss, granulite, lherzolite and in regions of contact metamorphism and secondary bedding formations (picotite), olivine-basalt and serpentine. Spinels are insoluble in hydrochloric acid. H., 8. Sp. gr., 3.5 to 4.1.

GARNET.

ISOTROPIC. ISOMETRIC.

COMPOSITION: R″_{3}R■_{2}(SiO_{4})_{3}. R″ is Ca, Mg, Fe or Mn; R■ is Al, Fe■, or Cr, rarely Ti.

■Usual Appearance in Sections■: Irregular grains, Fig. 13, or simple crystals, showing forms (110) and (211), alone or in combination, Fig. 14 _b_. Zonal structure not infrequent, especially in the titanium varieties, Fig. 34.

Color.—Colorless, or nearly so, to yellowish, reddish or brownish.

Index of Refraction.—_n_ = 1.750–1.856, hence _relief_ high and surface very rough.

Fracture.—Irregular cracks occur, but no cleavage noticed.

■Crossed Nicols■: As garnets are isotropic, sections remain dark during complete rotation. Optical anomalies may however occur, but are generally confined to, titanium free, lime garnets and manganese garnets. The effect being to divide the crystal symmetrically into different areas, “dodecahedral structure.”

[Illustration:

FIG. 34.—Garnet, with zonal structure, in gneiss. (From Cohen.)]

■Alteration■: Garnets are usually fresh, but may be found altered to chlorite or hornblende.

■Distinguished from■: SPINEL and PEROVSKITE.—See under the latter.

REMARKS: Found principally in granulites, metamorphic rocks, contact rocks, crystalline schists, etc. Certain varieties may be found in eruptive rocks or olivine rocks. May form pegmatitic borders with pyroxene, spinel, etc. Garnets are practically insoluble in hydrochloric acid. H., 6.5 to 7.5. Sp. gr., 3.4 to 4.3. The insolubility in acids and the high sp. gr. help in separating garnet from a powdered rock.

LEUCITE.

ISOTROPIC. ISOMETRIC.[80]

COMPOSITION: KAl(SiO_{3})_{2}.

■Usual Appearance in Sections■: Crystals or grains, which vary greatly in size. Cross-sections often nearly round. When very small and free from inclusions may be easily overlooked. Sometimes the grains are surrounded by tangentially arranged needles of different minerals.

[Illustration:

FIG. 35.—Leucite, with radial and tangential inclusions, Vesuvius Lava. (From Cohen.)]

Color.—Colorless.

Index of Refraction.—_n_ = 1.509, hence no _relief_ and generally smooth surface.

Fracture.—May be noticed, but no cleavage observed.

Inclusions.—Common, radially or zonally arranged, consisting of minerals or glass, Fig. 35.

■Crossed Nicols■: The smaller crystals appear isotropic; the larger crystals show characteristic intersecting systems of twin lamellæ, Fig. 36.

[Illustration:

FIG. 36.—Leucite, showing complicated, interpenetration twinning between crossed nicols.]

Double Refraction.—Very weak ($\gamma - \alpha = 0.001$). In thin sections it may be necessary to use a sensitive color plate to prove double refraction.

Interference Colors.—Very low 1st order, dark gray, etc.

■Alteration■: Quite frequent to fibrous or granular zeolites.

■Distinguished from■: ANALCITE—see under analcite.

REMARKS: Almost entirely confined to younger eruptive rocks, phonolite, tephrite and other leucite rocks and their tuffs. Often found with plagioclase, nephelite, augite, etc. It is more or less attacked by hot hydrochloric acid. H., 5.5 to 6. Sp. gr., 2.4 to 2.5. The isolation of leucite from rock powder can be better accomplished by specific gravity than by chemical methods.

ANALCITE.

ISOTROPIC. ISOMETRIC.

COMPOSITION: $NaAlSi_{2}O_{6} + H_{2}O$.

■Usual Appearance in Sections■: Secondary colorless grains, with no very characteristic microstructure or properties. Cleavage parallel to cube (100) usually seen. Index of refraction low (n = 1.488), hence rather rough surface. Between _crossed nicols_ may show optical anomalies, but not so marked as in garnet.

Distinguished from: LEUCITE, SODALITE and NEPHELITE. These minerals are most easily confused with analcite and recourse must be had to chemical tests, detection of optical anomalies, gelatinization test or turbidity by heating.

REMARKS: Occurs as a secondary product (commonly from nephelite or leucite) in alkali-rich eruptive rocks. Considered also as a primary mineral in igneous rocks.[81] Gelatinizes with hydrochloric acid, and becomes turbid by heating. H., 5.5. Sp. gr., 2.25.

SODALITE GROUP. Sodalite, Haüynite (Haüyne) and Noselite (Nosean).

ISOTROPIC. ISOMETRIC.

COMPOSITION:

Sodalite, $3NaAlSiO_{4} + NaCl$. Haüynite, $2(Na_{2}Ca)Al_{2}(SiO_{4})_{2} + (Na_{2}Ca)SO_{4}$. Noselite, $2Na_{2}Al_{2}Si_{2}O_{8} + Na_{2}SO_{4}$.

■Usual Appearance in Sections■: Dodecahedral rounded crystals or (S) irregular grains. Colorless, yellowish, brownish, greenish to deep blue. Refractive index low [n = 1.483(S) to 1.503(H)], hence the surface appears rather rough in sodalite and slightly rough in haüynite. Inclusions, abundant and characteristic, often rod-like and arranged regularly, making section translucent and especially dark at border, Fig. 37. Dodecahedral cleavage sometimes seen. Optical anomalies may occur.

■Alteration■: Takes place easily to aggregates of natrolite, other zeolites, mica, etc.

■Distinguished from■:

(_a_) ONE ANOTHER only by chemical tests. Gelatinization test with hydrochloric acid will show in addition to jelly, salt crystals for (S), abundant gypsum crystals ($CaSO_{2} + 2H_{2}O$) for (H) and few if any gypsum crystals (absence of Ca) for (N). (H) and (N) turn blue when heated, but test will not work if minerals are decomposed. When treated with hydrochloric acid and nitrate of silver the black sulphide of silver will show on (H) and (N), but the white chloride on (S).

(_b_) NEPHELITE (Elæolite) by being isotropic.

(_c_) ANALCITE by no turbidity when heated.

REMARKS: These minerals are found in the basic, soda-rich rocks. (S) in elæolite-syenite also in trachyte and phonolite, (H) and (N) common in phonolite and leucite-porphyry. H., 5.5 to 6. Sp. gr., 2.3.

[Illustration:

FIG. 37.—Haüynite, showing dark centre and border, in nepelinite. (From Cohen.)]

PEROVSKITE, Perofskite.

ISOTROPIC. ISOMETRIC. COMPOSITION: $CaTiO_3$.

■Usual Appearance in Sections■: Microscopic, octahedral crystals or larger grains, pale brownish in color and not very transparent, darker colored in the larger grains. In reflected light grains appear yellowish with adamantine lustre. Refractive index very high (_n_ = 2.38), hence _relief_ very strong.

Between _crossed nicols_, the little crystals generally appear optically normal and remain dark; but the larger crystals may show a complicated penetration twinning.

■Distinguished from■: GARNET (melanite) and SPINEL (picotite) by much higher refractive index and reaction for titanium and by zonal coloration of melanite. When opaque it might be mistaken for the iron ores, but has no metallic lustre.

REMARKS: Found in the younger basic eruptive rocks, especially melilite-basalt. Commonly associated with the iron ores nephelite, augite and chrysolite. Insoluble in hydrochloric acid. H., 5.5. Sp. gr., 4.1.

RUTILE.

ANISOTROPIC. UNIAXIAL. TETRAGONAL. COMPOSITION: TiO_2. _■_ = c ELONGATION ■ _■_.

■Usual Appearance in Sections■: Sharp, elongated, prismatic crystals when microscopic, but granular when the individuals are large. Grains may be almost opaque, with adamantine lustre by reflected light. Knee- or heart-shaped twins, Figs. 38 and 39, common in the smaller crystals, the larger individuals may also show geniculated twinning. Small crystals sometimes form net-shaped groups (sagenite), by crossing one another at angles of 60°. Pleochroic halos may surround crystals. Color, yellowish to reddish-brown. Index of refraction very high (_n′_ = 2.712, α = 2.616, γ = 2.903), hence _relief_ marked and surface very rough. Prismatic cleavage present in larger individuals, not observed in microscopic crystals. Pleochroism and strong absorption may be noticed, especially in the larger grains, but may fail entirely.

■Crossed Nicols■: Double refraction _very_ strong ($\gamma - \alpha$ = 0.287). Interference colors[82] very high order, only seen in the microlitic crystals which do not appear dark due to total reflection; in other cases may not show at all. _Extinction_ parallel to prisms. In _convergent light_ optical character (+).

■Alteration■: May take place to a white or yellowish, fibrous or granular substance, strongly refracting, and similar to the alteration product of ilmenite. May be surrounded by grains of titanite.

■Distinguished from■: The OPAQUE ORES by adamantine lustre with reflected light; ZIRCON and CASSITERITE in concentrates by chemical tests. May not be possible to distinguish from cassiterite in sections.

REMARKS: Found in the metamorphic schists, amphibolites, slates, contact and fragmentary rocks, etc.; also as inclusions in quartz and mica. Especially common as a secondary product of titaniferous hornblende and biotite. The “sagenite” webs of the decomposed micas are probably secondary. Rutile is insoluble in hydrochloric acid. H., 6 to 6.5. Sp. gr., 4.2. It is easily separated from rock powder by its insolubility in acid and its high sp. gr.

[Illustration:

Rutile twins.

FIG. 38.—Twin plane (101). FIG. 39.—Twin plane (301).]

ZIRCON.

ANISOTROPIC. UNIAXIAL. TETRAGONAL. COMPOSITION: $ZrSiO_4$. _c_ = ■. ELONGATION ■ c′.

■Usual Appearance in Sections■: Small, short prismatic crystals, Fig. 33A, and grains. Shell-like (zonal) structure may be noticed. When enclosed in black-mica, hornblende, cordierite, etc., often surrounded by characteristic pleochroic halos.[83]

Color.—Colorless, rarely pale brownish.

Index of Refraction.—_n′_ = 1.95, (α = 1.931, γ = 1.993) hence _relief_ very high and surface rough.

■Polarized Light■:

Pleochroism.—Not usually noticeable.

■_Crossed Nicols_■:

Double Refraction.—Very strong ($\gamma - \alpha = 0.062$).

Interference Colors.—Very high (4th) order, minute crystals show brilliant colors.

Extinction.—As zircon is uniaxial, basal sections remain dark during rotation of stage. In all other sections extinction is parallel to _■_.

■_Convergent Light_■: Basal sections, which are large enough to give interference figures, show several rings in addition to dark cross. Optical character (+).

■Alteration■: Very rarely takes place.

■Distinguished from■:

(_a_) APATITE.—By much higher relief and stronger double refraction.

(_b_) TITANITE.—By uniaxial character.

(_c_) RUTILE.—See under the latter.

Easily confused with xenotime, which, however, has higher interference colors and more distinct pleochroism; but chemical tests may be necessary.

REMARKS: Found widely distributed but not in quantity in eruptive and metamorphic rocks. Occurs in granite, syenite, diorite, gabbro, gneiss, etc. It is one of the oldest constituents of the rocks in which it occurs, and may often be found as inclusions in the ferro-magnesium minerals. Zircon is insoluble in hydrochloric acid. H., 7.5. Sp. gr., 4.5 to 4.7. It can easily be separated from rock powder on account of its high sp. gr., insolubility in acid and non-magnetic properties. The crystals can then be examined separately, or chemical tests made to prove the presence of Zr.

SCAPOLITE GROUP, Wernerite, etc.

ANISOTROPIC. UNIAXIAL. TETRAGONAL. COMPOSITION: Silicates of Ca, Al _■_ = a. ELONGATION ■ a′. and Na.

■Usual Appearance in Sections■: Colorless grains, lath-like individuals or prisms (dipyre, in contact metamorphic limestone). Index of refraction (_n′_ = 1.551 to 1.584;, $\alpha = 1.542$ to 1.558, $\gamma = 1.555$ to 1.597) about the same as quartz, hence usually no _relief_ and surface smooth. Cleavage distinct parallel to square prism. Inclusions (carbonaceous) may be abundant in contact rocks.

■Crossed Nicols■: Double refraction usually strong, but varies ($\gamma - \alpha = 0.013$ to 0.039), increases with the Ca percentage. Interference colors upper 1st or 2d order, more brilliant than those of most of the colorless minerals. Basal sections (showing cleavages intersecting at 90°) isotropic. _Extinction_ parallel in longitudinal sections. In _convergent light_ basal sections show distinct uniaxial interference figure; optical character (–).

■Alteration■: Takes place easily to a fibrous substance or to kaolin, muscovite, etc.

■Distinguished from■:

(_a_) FELDSPARS (not showing twinning) and IOLITE (Cordierite) by uniaxial character, cleavage and higher order interference colors.

(_b_) QUARTZ by cleavage, higher order interference colors and optical character; quartz is (+)

(_c_) APATITE (in grains) by lower index of refraction, cleavage and higher order interference colors.

REMARKS: Found especially in metamorphosed diabases and gabbros (Norwegian); also in gneisses, crystalline schists, metamorphosed limestones, etc. Dipyre occurs in contact zones of limestones and schists, where it might be confused with andalusite, but cross-sections show uniaxial character. The minerals of this group are more or less soluble in hydrochloric acid. When the scapolite contains Cl, the following test can be made on fresh material. Treat with a solution of silver nitrate in hydrofluoric acid and the jelly will be impregnated with chloride of silver which will turn brown. H., 5.5. Sp. gr., 2.68.

VESUVIANITE, Idocrase.

ANISOTROPIC. UNIAXIAL. TETRAGONAL. COMPOSITION: _■_ = a. ELONGATION ■ a′. $Ca_{6}Al_{3}(OH.F)(SiO_{4})_{6}$.

■Usual Appearance in Sections■: Grains or prismatic crystals. Almost colorless to reddish (when containing Mn). Index of refraction high (_n′_ = 1.715, α = 1.701 to 1.726, γ = 1.705 to 1.732), hence _relief_ marked and surface rough. Cleavage imperfect, parallel to prism. Pleochroism generally very faint.

■Crossed Nicols■: Double refraction very weak ($\gamma - \alpha$ = 0.001 to 0.006), may vary in different portions of the same crystal (optical anomalies due to the mineral being at times a mixture of isomorphous individuals). Interference colors very low 1st order, dark gray, etc., may often appear zonal. Basal sections isotropic when normal, but may show division into biaxial portions. _Extinction_ parallel in sections elongated ■ _■_ axis. In convergent light basal sections show a faint cross when normal; optical character generally (–).

■Alteration■: Not known in rock-making vesuvianite.

■Distinguished from■: EPIDOTE (Pistacite) by the very low order interference colors. CORUNDUM by weaker double refraction. GARNET (Grossularite), ZOISITE, and APATITE may be easily confused with this mineral and hard to distinguish from it.

REMARKS: Found in limestones, that have undergone alteration by contact with igneous rocks, and in metamorphic schists. Also may occur in dense (nephrite-like) aggregates in serpentine. It is insoluble in hydrochloric acid. H., 6.5. Sp. gr., 3.3 to 3.8.

MELILITE.

ANISOTROPIC. UNIAXIAL. TETRAGONAL. COMPOSITION: $Na_{2}(Ca,Mg)_{11}(Al,Fe)_{4}Si_{9}O_{36}$?. _■_ = a. ELONGATION ■ c′.

■Usual Appearance in Sections■: Almost colorless, tabular (■ base) crystals or irregular grains or shreds. Sections very commonly lath-shaped, and often characterized by the peculiar “peg-structure,”[84] the lines or markings being ■ _■_ (■ elongation of the section). Index of refraction (_n′_ = 1.630, α = 1.629, γ = 1.631) higher than that of the other associated colorless materials, hence _relief_ rather marked. Cleavage, parallel to base, very imperfect.

■Crossed Nicols■: Double refraction very weak ($\gamma - \alpha$ = 0.003), and diminishes with a decrease of Al. Interference colors the lower 1st order, grays, etc.; anomalous interference colors may show. _Extinction_ parallel to cleavage or the peculiar markings or lines. Optical character usually (–), but when poor in Al (+).

■Alteration■: Takes place frequently to a fibrous aggregate.

■Distinguished from■: NEPHELITE and FELDSPAR by higher relief, shape, “peg-structure” and usual dull appearance with reflected light.

REMARKS: Abundant in the leucite and nephelite rocks (associated with these minerals and with augite, perovskite and chrysolite), and takes the place of a feldspar in the melilite-basalt. It gelatinizes easily with hydrochloric acid. H., 5. Sp. gr., 2.9.

GRAPHITE.

HEXAGONAL.

COMPOSITION: C.

■Usual Appearance in Sections■: Minute particles, or flakes and grains of irregular shape, seldom crystallized.

Opaque, and by reflected light, black with metallic lustre.

■Distinguished from■: The similarly appearing ores by its insolubility in acids and the possibility of making it disappear by heating.

REMARKS: Graphite is widely distributed in the oldest rock formations, especially in the schists. It is often associated with rutile and the iron oxides. Graphite is not acted on by acids. H., 1 to 2. Sp. gr., 2.09 to 2.25. It is burnt with great difficulty in thin sections on platinum foil; but this test may vary, in many cases the graphite (when in bladed flakes) not being consumed even after long heating. When heated it may expand into worm-like forms.

Carbonaceous Matter.—Occurs in opaque, grayish-black particles having no lustre; and is found finely disseminated, sometimes in larger aggregations, in clay slates, limestones, etc.

HEMATITE.

HEXAGONAL.

COMPOSITION: $Fe_{2}O_{3}$.

■Usual Appearance in Sections■: Irregular scales, minute grains or earthy. Distinct crystalline forms not often observed in rocks.

Opaque, and by reflected light, black with metallic lustre, or red without lustre. May also be transparent in red tints. No marked pleochroism observed.

REMARKS: Found widely distributed in acid eruptive rocks, crystalline schists, etc. Also as inclusions in minerals, and as a red pigment in many rocks. It is insoluble in hydrochloric acid, and non-magnetic, unless attached to grains of magnetite. H., 5.5 to 6.5. Sp. gr., 4.9 to 5.3.

ILMENITE, Menaccanite.

HEXAGONAL.

COMPOSITION: $(FeTi)_{2}O_{3}$.

■Usual Appearance in Sections■: Irregular masses, without crystallographic outline, rhombohedral crystals, or skeleton-like growths. Also in brownish, translucent mica-like forms.

Opaque, and by reflected light, iron-black with metallic lustre.

When _translucent_: pleochroism brown to yellow; double refraction not very strong; optically (–).

■Alteration■: Often takes place to a whitish, strongly refracting, substance only slightly transparent, called _leucoxene_. This alteration product frequently develops along definite rhombohedral directions, Fig. 33 C. Also a change to titanite or rutile may occur, or the ilmenite may be surrounded by these minerals.

■Distinguished from■: MAGNETITE and HEMATITE.—By whitish, strongly refracting decomposition product. At times the distinction may be very difficult.

REMARKS: Ilmenite occurs principally in the soda-rich and basic eruptive rocks. The mica-like form is limited to the porphyritic eruptives. The brown pigment in the plagioclase of certain gabbros may be ilmenite. It is attacked slowly by hot hydrochloric acid, and the solution when heated with tin becomes violet. Pure ilmenite is indifferent towards the magnet, hence strong magnetic properties would indicate a mixture with magnetite. H., 5 to 6. Sp. gr., 4.5 to 5.

CORUNDUM.

ANISOTROPIC. UNIAXIAL. HEXAGONAL. COMPOSITION: $Al_{2}O_{3}$. _c_ = a.

■Usual Appearance in Sections■: Pyramidal or prismatic crystals, grains or basal plates. Zonal structure or twinning may be noticed. Colorless or with patches of blue. Index of refraction high (_n′_ = 1.766, α = 1.760, γ = 1.769), hence _relief_ well marked and surface very rough. Rhombohedral cleavage may show in larger individuals. Pleochroism only marked when color is deep.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha = 0.009$), like quartz. Interference colors middle 1st order, white to yellow. _Extinction_ parallel in elongated sections. Optical anomalies very rarely noticed in microscopic individuals. In _convergent light_ basal sections show a rather indistinct cross; optical character (–).

■Distinguished from■:

(_a_) APATITE and VESUVIANITE by brighter interference colors.

(_b_) TOURMALINE (light colored) by not having such strong absorption.

(_c_) CYANITE by uniaxial character.

Corundum may need to be isolated from the rock in order to be determined with certainty.

REMARKS: found in contact metamorphic rocks, eruptive rocks, granular limestones, etc. It is insoluble in hydrochloric acid. When rock sections are ground with emery, care must be taken not to confuse grains of emery with corundum in the rock. H., 9. Sp. gr., 3.9 to 4.

QUARTZ.

ANISOTROPIC. UNIAXIAL. HEXAGONAL. COMPOSITION: SiO_{2}. _■_ = c.

■Usual Appearance in Sections:■ Allotriomorphic in the granitoid rocks, when apparently the last mineral to form, Fig. 5. More or less chemically corroded pyramidal crystals (with cross-sections six-sided or rhombic with an angle of about 100°) in the porphyritic rocks. Rounded or angular grains in the “clastic” rocks; granular mosaic in crystalline schists and contact rocks, very rarely in distinct crystals in any rocks. May at times be mutually interpenetrated with an acid feldspar (the areas of quartz and feldspar extinguishing as entire crystals), producing “micro-pegmatitic” structure, Fig. 67. Finally may appear as pseudomorphs after other minerals, but may then consist of some of the other forms of silica.

Color.—Colorless, although by reflected light it may appear colored or cloudy if it contain many inclusions.

Index of Refraction.—_n′_ = 1.547 ($\alpha = 1.544$, $\gamma = 1.553$) hence no _relief_ and surface smooth.

Cleavage..—Rarely noticed, an important fact in determining quartz. Quartz breaks irregularly.

Inclusions.—Minute fluid, gas and mineral inclusions, often in irregular trains, are very characteristic of quartz in granite rocks and crystalline schists. The inclusions are not so abundant in porphyritic rocks, but a few glass inclusions may occur, filling up “negative” crystals in the quartz. Rutile, amphibole, etc., may occur as needle-like inclusions in quartz.

Polarized Light:

Pleochroism.—None.

■Crossed Nicols:■

Double Refraction.—Weak ($\gamma - \alpha = 0.009$).

Interference Colors.—The middle 1st order, white, yellow, etc.

Extinction.—As quartz is uniaxial, basal sections remain dark during a complete rotation of stage. In the other sections extinction is not characteristic, due to the absence of cleavage and crystallographic outlines. Thin sections do not show circular polarization.

■Convergent Light:■ Basal sections show a dark cross, without any rings. Optical character (+).

■Alteration:■ Does not take place, so quartz always appears fresh and unweathered in sections.

■Distinguished from:■

(_a_) SANIDINE (in fresh grains).—By use of convergent light. Feldspar is biaxial, or sections which appear uniaxial are (–).

(_b_) NEPHELITE.—By almost entire absence of hexagonal outline, stronger double refraction, fresh, unweathered appearance and (+) optical character.

(_c_) IOLITE (Cordierite), SCAPOLITE and TOPAZ.—See under the latter minerals.

Quartz may be distinguished from all silicates by being dissolved without residue in hydrofluoric acid.

REMARKS: Quartz occurs widely distributed, as in the great sandstone formations. It is also a characteristic mineral of all acidic rocks, being common in granite, aplite, rhyolite, quartz-porphyry, quartz-diorite, dacite, etc. Quartz is very brittle and hence is a good indicator of the dynamic forces which have affected the rocks. It may show traces of mechanical deformation by peripheral shattering of the larger grains or by "wavy extinction";[85] and also evidences of chemical corrosion by curved and looped contours. In some diabases the quartz may be surrounded by a rim of hornblende or augite needles ("quartz augen"). "Cataclastic" quartz may be biaxial. The "secondary enlargement" of quartz in clastic rocks may be noticed by the deposition of silica in crystallographic orientation around the clastic grains,[86] the new portion extinguishing at the same time as the core. Quartz is not attacked by ordinary acids. H., 7. Sp. gr., 2.6 to 2.7.

Chalcedony.—This variety of SiO_{2} has a radially fibrous structure and shelly parting. It may form sphærulites, central sections through which show a dark cross between crossed nicols, or line cavities in rocks.

The index of refraction is a little lower than for ordinary quartz. The optical character is (–), which must be determined by a mica or gypsum plate, _■_ = a. Elongation ■ a′.

Chalcedony occurs in the ground mass of very silicious porphyritic rocks, which have microfelsitic development; and is found as a secondary mineral in all kinds of silicate rocks.

TRIDYMITE.

■Usual Appearance in Sections■: This form of SiO_{2}, which is soluble in boiling caustic soda, appears in "tile-like" aggregates of minute colorless plates (pseudo-hexagonal) and is always secondary. The refractive index is extremely low (_n′_ = 1.477), hence the surface appears rough.

Between _crossed nicols_ the interference colors are very low in order (γ-α = 0.002), and the tablets may show a division into different areas (optical anomalies). In _convergent light_ an indistinct biaxial figure is generally seen.

REMARKS: Chiefly a volcanic mineral, found in rhyolite, trachyte and andesite. Commonly associated with opal and chalcedony.

CALCITE.

ANISOTROPIC. UNIAXIAL. HEXAGONAL.

COMPOSITION: CaCO_{3}. Ca may be replaced by small quantities of Mg, Fe, Mn, etc. _■_ = a.

■Usual Appearance in Sections:■ Grains and aggregates. May be fibrous or oölitic. Only in crystals in certain rocks.[87]

[Illustration:

FIG. 40.—Calcite, crossed twin lamellæ, in granular limestone. (From Cohen.)]

Twinning.—Polysynthetic, parallel to one or more faces of –½ R. (10■12). Very common in crystalline limestones, and may have been produced by pressure or by the grinding of the section. Shows itself between crossed nicols as a series of light and dark bands, parallel or intersecting, Fig. 40, about parallel to longer diagonal of cleavage rhombs. When the composition face of the twins is oblique to the face of the section, interference colors can be seen without the analyzer.

Color.—Colorless when pure, but may appear colored by transmitted light, due to organic pigments.

Index of Refraction.—_n′_ = 1.601 (α = 1.487, γ = 1.659) hence with ordinary light _relief_ not marked. Due to the great variation in refractive indices of the two rays, with polarized light, the surface will appear either quite smooth or rather rough, depending upon which vibration direction lies over the plane of the polarizer. This marked variation in appearance (sometimes called "twinkling") serves as a good test for calcite.

[Illustration:

FIG. 41.—Calcite, section parallel to face of rhombohedron, showing rhombohedral cleavage. (From Cohen.)]

Cleavage.—Parallel to unit rhombohedron (10■11), appearing in thin sections as many sharp cracks, whose angles of intersection depend on the position of the section, Fig. 41. Newton's colors may be seen along cleavage cracks.

■Polarized Light:■

Pleochroism.—None.

■Crossed Nicols:■

Double Refraction.—Very strong ($\gamma - \alpha = 0.172$).

Interference Colors.—Pale, iridescent colors of very high order.

Extinction.—As calcite is uniaxial, basal sections remain dark during rotation. Extinction angles with respect to the cleavage cracks vary with the position of the section.

■Convergent Light:■ Basal sections, even when very thin, show distinct interference figure, with cross and rings. Optical character (–).

■Distinguished from■:

(_a_) Other CARBONATES.—By ease with which it is attacked by cold dilute acids, test can be made on slide after removing cover.

(_b_) MAGNESIUM-BEARING CALCITE.—By micro-chemical tests.

(_c_) TITANITE (Sphene).—See under the latter.

REMARKS: Calcite is very widely distributed, in addition to the extensive sedimentary limestone deposits. Common limestone consists of dense aggregates of crystalline grains. Calcite is often a secondary product of the lime-bearing silicates in the more basic eruptive rocks. Pseudomorphs of calcite after olivine are noteworthy. Coarse aggregates of calcite occur in the crystalline schists and contact rocks. Calcite is exceedingly plastic to pressure and mechanical deformation may be recognized by curving of the cleavage cracks, crumpling of the twin lamellæ and "wavy" extinction. Calcite is easily attacked and completely dissolved with effervescence by cold dilute acids. H., 3. Sp. gr., 2.72.

DOLOMITE.

ANISOTROPIC. UNIAXIAL. HEXAGONAL.

COMPOSITION: $CaMg(CO_{3})_{2}$, when pure CaO = 30.4, MgO = 21.7, CO_{2} = 47.8. Proportions of Mg and Ca vary, and Fe and Mn also occur. _■_ = α.

■Usual Appearance in Sections:■ In rocks chiefly as crystals, even dense homogeneous aggregates showing tendency towards crystalline boundaries (saccharoidal structure). Crystals almost always unit rhombohedron (10■11) with tendency to curved surfaces.

Index of Refraction.—_n′_ = 1.622 (α = 1.503, γ = 1.682, $\gamma - \alpha = 0.179$), a little higher than that of calcite. For variation in appearance of surface with polarized light, see under calcite.

The microscopic characters are similar to those of calcite, from which it may be _distinguished_ by not being so easily attacked by cold dilute acid (test can be made on slide with cover off), by tendency towards crystalline boundaries, by absence of twin lamellæ (or when present parallel to _–2R._ (20■21), hence about parallel to shorter diagonals of cleavage rhombs), and by micro-chemical tests. The distinction at times may be very difficult.

REMARKS: Occurs in sedimentary formations and as crystals in limestone and other rocks. In certain rocks the dolomite crystals may not have a very good "bond," and a "drusy" structure may also be characteristic of the cavities between dolomite crystals in rocks. Only slightly attacked by cold dilute acids, but if acid is heated it dissolves easily with effervescence.

APATITE.

ANISOTROPIC. UNIAXIAL. HEXAGONAL. COMPOSITION: _■_ = a. ELONGATION ■ a′. $Ca_{5}(Cl.F)(PO_{4})_{3}$.

■Usual Appearance in Sections■: Minute, slender hexagonal prisms, cross-sections having regular hexagonal boundaries, needles, and grains. Figs. 14 _a_ and 42.

[Illustration:

FIG. 42.—Apatite, showing cross fracture, in nepheline-basalt. (From Cohen.)]

Color.—Generally colorless, seldom bluish or brownish (only in eruptive rocks).

Index of Refraction.—_n′_ = 1.635 (α = 1.634, γ = 1.637), hence _relief_ more marked than that of the colorless associated minerals.

Cleavage.—Seldom observed microscopically.

Parting.—Long columnar crystals generally show a transverse jointing, so that the pieces may be more or less separated.

Inclusions.—Gas and fluid may be present.

■Polarized Light■:

Pleochroism.—None shown by the colorless crystals, the colored crystals show stronger absorption parallel to _■_.

■Crossed Nicols■:

Double Refraction.—Weak ($\gamma - \alpha$ = 0.003).

Interference Colors.—The lower first order, generally grayish-blue or white.

Extinction.—As apatite is uniaxial, basal sections remain dark during rotation of stage. In all other sections extinction is parallel to _■_ axis.

■_Convergent light_■: Basal sections show a cross, without rings. Optical character (–).

■Alteration■: Does not usually take place, apatite being found perfectly fresh in decomposed rocks, which is quite remarkable considering its easy solubility in acids.

■Distinguished from■:

(_a_) SILLIMANITE and TREMOLITE.—By weak double refraction and elongation ■ a′.

(_b_) NEPHELITE.—By being relatively much smaller and longer than the nephelite crystals, which are often decomposed. Also by higher relief and negative results with gelatinization test.

(_c_) ZIRCON.—By lower relief and much weaker double refraction.

(_d_) FELDSPARS (when granular and undecomposed).—By higher relief and uniaxial interference figure.

(_e_) VESUVIANITE and ZOISITE.—May be only possible by chemical tests.

(_f_) CORUNDUM.—See under the latter.

REMARKS: Found in most igneous rocks and crystalline schists. In the eruptive rocks it appears as one of the oldest secretions from the magma, and hence is often found as inclusions in other minerals, especially biotite, hornblende, etc. Apatite is easily soluble in hydrochloric and nitric acids. H., 4.5 to 5. Sp. gr., 3.19. On account of its high sp. gr., apatite, in rock powder, comes down in heavy solutions with the metallic minerals, and can be separated from them by the use of a magnet. This residue can also be tested for phosphorus in the wet way with ammonium molybdate.

NEPHELITE,[88] Nepheline, Elæolite.

ANISOTROPIC. UNIAXIAL. HEXAGONAL. COMPOSITION: 7NaAlSiO_{4} + _■_ = α. NaAl(SiO_{3})_{2}, with partial replacement of Na by K.

■Usual Appearance in Sections■: Nephelite in short hexagonal prisms and grains in the younger volcanic rocks, hence sections rectangular or hexagonal, Fig. 43; elæolite allotriomorphic in the older plutonic rocks.

Color.—Colorless.

Index of Refraction.—_n′_ = 1.539 (α = 1.538, γ = 1.542), hence no relief and surface smooth.

Cleavage.—Imperfect, parallel to prism (10■10) and base (0001). More marked in elæolite than in nephelite, especially when decomposition has commenced.

[Illustration:

FIG. 43.—Nephelite sections, showing zonal inclusions. (From Reinisch.)]

Inclusions.—Microscopic needles of augite, etc., also fluid and gas. Mostly in zones. Elæolite may be much clouded by inclusions and alteration products.

■Polarized Light■:

Pleochroism.—None.

■Crossed Nicols■:

Double Refraction.—Very weak (γ – α = 0.004), may only be detected by using a test-plate.

Interference Colors.—The lower first order, grayish-white, etc., a little lower than the feldspar colors.

Extinction.—As the mineral is uniaxial, basal sections remain dark during rotation of stage. In all other sections extinction takes place and is parallel to cleavage lines when these appear.

■Convergent Light■: Basal sections show a broad cross, without rings. Optical character (–).

■Alteration■: Takes place easily to fibrous zeolites (natrolite), or in certain rocks to mica.

■Distinguished from■: OTHER MINERALS by gelatinization test and staining with fuchsine. When present in small interstitial individuals (as is often the case in basalts) it is very difficult to distinguish without this test; but it must be remembered that other minerals, zeolites, etc., will also gelatinize. QUARTZ has stronger double refraction, rarely shows hexagonal outline, is always fresh and optically (+). FELDSPAR is biaxial and often shows twinning. ANALCITE.—See under the latter.

REMARKS: Nephelite bears the same relation to elæolite as sanidine does to orthoclase. It occurs only in the younger volcanic rocks; with sanidine in phonolite, with plagioclase in tephrite, without feldspar in nepheline-basalt, and with leucite in leucite-basalt. It is not found with primary quartz. Elæolite occurs with orthoclase in elæolite-syenite, etc. nephelite and elæolite frequently occur with the sodalite group. Nephelite gelatinizes with acids. H., 5.5 to 6. Sp. gr., 2.5 to 2.6.

TOURMALINE, Schorl.

ANISOTROPIC. UNIAXIAL. HEXAGONAL. COMPOSITION: Uncertain, _■_ = a. ELONGATION ■ a′. R_{18}B_{2}(SiO_{5})_{4}. R chiefly Al, K, Mn, Ca, Mg, Li.

■Usual Appearance in Sections■: Staff-like individuals, bunched or in radiating aggregates, Fig. 44 B, or prismatic crystals, Fig. 44 A. Basal sections may be nine-sided.

Color.—Varies greatly, grayish-blue, brown and green most common. Li-tourmaline (rare in rocks) is colorless. Zonal structure may be indicated by differences in color.

[Illustration:

FIG. 44.—_A_, Tourmaline, showing strong absorption at right angles to direction of elongation (_P_ = plane of vibration of polarizer). _Quartzite_, Black Hills, D. _B_, Tourmaline in radiate aggregate. _Granite_, Cornwall.]

Index of Refraction.—_n′_ = 1.633 (precious) to 1.674 (α = 1.620 to 1.651, γ = 1.640 to 1.685), hence _relief_ is marked and surface rough.

Cleavage.—Not seen in thin sections, but irregular, transverse and longitudinal cracks may appear.

■Polarized Light■:

Pleochroism.—Distinct, even in light colored varieties, increasing with the depth of color. The greatest absorption takes place at right angles to the direction of elongation of the crystal, Fig. 44 A. The other minerals having this very strong absorption are hornblende, dark colored mica (distinguished by cleavage and lamellar form) and allanite. Pleochroic halos may be noticed surrounding inclusions.

■_Crossed Nicols_■:

Double Refraction.—Quite strong ($\gamma - \alpha$ = 0.017 (precious) to 0.034).

Interference Colors.—Bright upper first or second order, but may not be noticeable, due to absorption of parts of the light.

Extinction.—As tourmaline is uniaxial, basal sections remain dark during rotation of stage. In all other sections extinction is parallel to _■_ axis.

■_Convergent Light_■: Cross-sections show a sharp cross. Optical character (–).

■Alteration■: Does not take place.

■Distinguished from■:

(_a_) HORNBLENDE.—By absence of cleavage, and by the fact that the greatest absorption takes place at right angles to the longitudinal axis, while in hornblende it takes place approximately parallel to the longitudinal axis, or to the cleavage lines which are parallel to this axis.

(_b_) APATITE (when colored).—By strong absorption at right angles to longitudinal axis.

(_c_) CORUNDUM.—See under the latter.

In some cases where recognition is difficult, chemical tests, to prove presence of boracic acid, must be made.

REMARKS: The black schorl is the only primary tourmaline and is found in granitoid rocks. Tourmaline in other rocks results from “fumarole” action; hence occurs in pegmatite, tin and copper veins, clay deposits, also (light colored) in contact rocks and crystalline schists. The hemimorphic terminations may sometimes be noticed. Tourmaline is not acted on by acids. H., 7 to 7.5. Sp. gr., 3 to 3.2. It can be separated from powdered rock by sp. gr. solutions combined with magnetic methods.

ANDALUSITE

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: Al_2SiO_5. _■_ = a. ELONGATION ■ a′.

■Usual Appearance in Sections■: In short, rounded, prismatic crystals, with almost square cross-section. Colorless or at times pale reddish and spotted. Index of refraction medium (_n′_ = 1.637, α = 1.632, γ = 1.643), hence _relief_ well marked and surface rough. Cleavage, parallel to almost square prism, may show. Pleochroism only marked in colored varieties, being reddish ■ _■_ (the direction of elongation or cleavage). Carbonaceous inclusions are characteristic, arranged as in macroscopic specimens (_Chiastolite_), Fig. 45. Pleochroic halos may surround inclusions.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha$ = 0.001). Interference colors middle 1st order, white to yellow. _Extinction_ in general parallel to _■_ axis in longitudinal sections, symmetrical in cross-sections. In _convergent light_ Ax. pl. ■ (010), Bx_{_a0_}. ■ _■_; axial angle very large (2_E_ > 180°); optical character (–).

■Alteration■: Often takes place to dense aggregate of mica, when the pseudomorph may be hard to recognize.

■Distinguished from■:

(_a_) SILLIMANITE by much weaker double refraction, less elongated crystals and by elongation ■ a′ (Sillimanite elong. ■ c′).

(_b_) DIOPSIDE by weaker double refraction, rhombic cross-section and parallel extinction in longitudinal sections.

REMARKS: Very characteristic of metamorphic schists and of contact zones of clay slates with granite, etc., but not found in rocks which have been formed at great pressure. The andalusite grains may often be arranged in divergent or finger-like manner. May also form parallel growths with sillimanite. It is insoluble in hydrochloric acid. H., 7 to 7.5. Sp. gr., 3.18.

[Illustration:

FIG. 45.—Chiastolite, showing characteristic carbonaceous inclusions. (From Cohen.)]

[Illustration:

FIG. 46.—Sillimanite aggregate, showing cross fracture, in mica schist. (From Cohen.)]

SILLIMANITE, Fibrolite.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: Al_2SiO_5. _c_ = c′. ELONGATION ■ c′.

■Usual Appearance in Sections■: Long, slender, colorless prisms or needles; often in felt-like aggregates. Crystals often bent. Index of refraction rather high (_n′_ = 1.664, α = 1.656, γ = 1.677), hence _relief_ marked. Transverse fractures common, Fig. 46.

■Crossed Nicols■: Double refraction rather strong ($\gamma - \alpha$ = 0.021). Interference colors upper first or lower second order, red, purple, blue, etc. _Extinction_ parallel to prisms. Ax. pl. ■ (100), Bx_{_a_}. ■ _■_, 2_E_ = 35° to 55°. Optical character (+).

■Distinguished from■:

(_a_) APATITE by higher order interference colors and by elongation ■ c′ (apatite has elongation ■ a′).

(_b_) TREMOLITE by always parallel extinction and small size of axial angle.

(_c_) ANDALUSITE, see under the latter mineral.

REMARKS: Found especially in clay-rich contact rocks, gneisses and schists, often occurring with iolite (cordierite). Crystals may appear in bands. It is insoluble in hydrochloric acid. H., 6 to 7. Sp. gr., 3.24.

TOPAZ.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: _■_ = c. $Al(Al(O.F_2))SiO_4$.

■Usual Appearance in Sections■: Colorless crystals of short prismatic habit, grains or rod-like radiating aggregates. Index of refraction about the same as that of calcite (_n′_= 1.608 to 1.632, α = 1.607 to 1.629, γ = 1.618 to 1.637), hence _relief_ medium. Cleavage perfect, parallel to base, but does not show as many cracks. Fluid inclusions abundant.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha$ = 0.008 to 0.011), about the same as that of quartz. Interference colors middle first order, white, yellow, etc. _Extinction_ parallel to cleavage. In _convergent light_, Ax. pl. ■ (010), Bx_{_a_}. ■ _■_, axial angle large (2_E_ = 86° to 126°); interference figure obtained from basal sections (_i. e._, from sections showing no cleavage); optical character (+).

■Alteration■: May take place to kaolin or muscovite, by loss of F and taking up of H_2O and alkalies.

■Distinguished from■:

(_a_) QUARTZ by higher relief, cleavage and biaxial character.

(_b_) SILLIMANITE (when topaz is in radiating aggregates) by lower refraction and double refraction.

REMARKS: Common in greisen and all granite rocks containing tin ore. When formed by “fumarole” action (tin veins) the mineral shows rod-like radiating forms. It is insoluble in hydrochloric acid. H., 8. Sp. gr., 3.5.

STAUROLITE.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: ELONGATION ■ ■. Fe(AlO)_{4}(AlOH)(SiO_{4})_{2}, but varying, may contain Mg or Mn. _■_ = c.

[Illustration:

FIG. 47.—Staurolite, showing twinning at 90° _b_ and 60° _c_, also granular quartz inclusions. (From Reinisch.)]

■Usual Appearance in Sections■: Short, flat prisms, which may be twinned at 90° or 60°, Fig. 47, or grains. Color yellowish to reddish-brown. Index of refraction rather high (_n′_ = 1.741, α = 1.736, γ = 1.746), hence _relief_ marked and surface rough. Cleavage, both prismatic and pinacoidal, variable. Inclusions of minute quartz grains and carbonaceous matter found in larger crystals, but not in microscopic crystals. Pleochroism distinct but not strong, showing red ■ _c_ (direction of elongation). Pleochroic halos may surround inclusions.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha$ = 0.010). Interference colors middle first order, white to yellow, etc. (about like quartz). _Extinction_ in general parallel or symmetrical (in cross-sections) to cleavages or crystal outline. In _convergent light_, Ax. pl. ■ (100), Fig. 48. Bx_{_a_}. ■_■_, axial angle large (2_E_ > 180°); optical character (+).

[Illustration:

FIG. 48.—Staurolite, cross-section.]

■Alteration■: Rarely takes place.

■Distinguished from■: TITANITE, see under the latter mineral.

REMARKS: Found in metamorphic schists, associated with cyanite (disthene), iolite (cordierite), andalusite, etc. It is one of the minerals produced by thermal metamorphism, hence found in rocks of granite contact zones. It does not occur in the eruptive rocks or in schists rich in amphibole. Staurolite is not acted on by hydrochloric acid. H., 7 to 7.5. Sp. gr., 3.4 to 3.8.

THE ORTHORHOMBIC PYROXENES. Enstatite and Hypersthene.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: (Mg.Fe)SiO_{3}. _■_ = c. ELONGATION ■ c′.

Enstatite contains little, if any, Fe. Hypersthene contains more Fe, its optical characters beginning to show with about 10 per cent.

[Illustration:

FIG. 49.—Enstatite, showing columnar or fibrous structure ■ _■_ axis. _Norite_, Harzburg.]

■Usual Appearance in Sections■: Irregularly bounded individuals (E) or rounded prismatic-pyramidal crystals (H). Columnar or fibrous structure ■ _■_ often shows in (E), Fig. 49. Prism angle about 92°. Outline of crystal sections very similar to that of monoclinic pyroxenes.

Twinning.—Not so common as in monoclinic pyroxenes. Parallel growths with monoclinic pyroxene (diallage) occur.[89]

Color.—Varies with Fe per cent., (E) colorless, (H) brownish.

Index of refraction.—_n′_ = 1.665 (E) to 1.723 (H) (α = 1.660 to 1.716, γ = 1.670 to 1.729) (about the same as in monoclinic pyroxene), hence _relief_ marked and surface rough.

Cleavage.—Variable, parallel to prism (angle 92°) common to all pyroxenes. Also cleavage or parting parallel to brachy pinacoid (010) (prominent) and macro pinacoid (100).[89]

Inclusions.—Parallel oriented, brownish plates and rods, producing “schiller” structure on the principal cleavage faces, Fig. 15. Glass inclusions abundant in (H).

■Polarized Light■:

Pleochroism.—Almost absent in (E), but distinct in (H), increasing with Fe per cent. The change in color may be very marked, from brownish-red to greenish ■ _■_.

■Crossed Nicols■:

Double Refraction.—Weak, much weaker than in the monoclinic pyroxenes, increasing with Fe per cent. ($\gamma - \alpha = 0.010$ (E) to 0.013 (H).)

Interference Colors.—Higher first order, about the same or a little higher than quartz.

Extinction.—Parallel to cleavages in longitudinal sections, which are parallel to _a_ or _b_, and bisecting angles of intersecting prismatic cleavages in basal sections.

■Convergent Light■: Axial plane parallel to brachy pinacoid (010),[89] _i. e._, parallel to best pinacoidal cleavage. Bx_{_a_}. ■ _■_ (E), ■ _a_(H). Axial angles large (2_E_ = 95° to > 180°). Optical character for (_E_)(+), for (_H_)(–). On account of weak double refraction the interference figures are not very marked.

■Alteration■: Takes place to bastite, serpentine, etc.

■Distinguished from■: The MONOCLINIC PYROXENES and AMPHIBOLES.—See under these species.

REMARKS: Found in the granular rocks of the gabbro-peridotite series, also in the olivine basalts (E); and in crystals in porphyritic andesite (H). These minerals are in general not attacked by acids. H., 5 to 6. Sp. gr., 3.1 to 3.5.

Bronzite is the name give to the variety containing about 5% Fe and having the characteristic bronzy lustre due to inclusions.

Bastite (an alteration product of the orthorhombic pyroxenes poor in Fe).—Composed of fibers, often traversed by irregular cracks. Color light yellowish or greenish and index of refraction about the same as Canada balsam. Pleochroism faint (only seen in thick sections), the greatest absorption taking place parallel to the fibers. Double refraction weak and extinction parallel to the fibers. Axial angle large and axial plane at right angles to principal cleavage face (010). The position of the axial plane is the surest distinction between bastite and the orthorhombic pyroxenes.

CHRYSOLITE, Olivine.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: (Mg.Fe)_{2}SiO_{4}. ELONGATION ■ a′ or c′.

■Usual Appearance in Sections■: Prismatic crystals or in large angular fragments or grains. Longitudinal sections more or less lath-shaped, with pointed ends, Figs. 50 and 51, cross-sections six or eight-sided. Outlines of crystals often rounded or corroded. Skeleton forms may occur, and sometimes twinning may be observed.

[Illustration:

Chrysolite.

FIG. 50. FIG. 51. Basal section. Macro pinacoid section.]

Color.—Nearly colorless, may be reddish (with high Fe per cent.).

Index of Refraction.—_n′_ = 1.675 ($\alpha = 1.661$, $\gamma = 1.697$), hence _relief_ marked and surface rough.

Cleavage.—Parallel to brachy pinacoid (010), less distinct parallel to macro pinacoid (100), Fig. 50. Often only made visible by decomposition. An irregular fracturing occurs, which increases with alteration into serpentine.

Inclusions.—Chromite, opaque earths, apatite and the brown plates so common in hypersthene; also glass and slag (in basaltic rocks) and fluid (in peridotites and olivinfels).

■Polarized Light■:

Pleochroism.—In general none, but noticed in the reddish varieties, when the absorption is a little stronger parallel to _■_.

■_Crossed Nicols_■:

Double Refraction.—Very strong ($\gamma - \alpha = 0.036$).

Interference Colors.—Rather high in order (second or third), higher than the colors of augite.

Extinction.—In general parallel to cleavage lines.

■Convergent Light■: Axial plane parallel to base (001) and always at right angles to cleavage cracks, Fig. 51. Bx_{_a_}. ■ _a_. Axial angle very large (2_E_ > 180°). Optical character (+).

■Alteration■: Into serpentine very common,[90] producing “mesh-” or “lattice-” structure (see under serpentine, p. 114); also into amphibole, etc. In certain basaltic rocks the rims of grains may be changed into gœthite?, and in certain gabbros the crystals may be surrounded by a radial rim of amphibole.

■Distinguished from■:

Light colored MONOCLINIC PYROXENES.— By the absence of extinction angles, cleavage (the intersecting prismatic cleavages of augite being of equal distinctness), stronger double refraction and by axial plane being parallel to base, hence always at right angles to best cleavage (in augite axial plane lies in clino pinacoid, bisecting angles of intersecting prismatic cleavages). Also by gelatinization with acids.

REMARKS: Found only in basic rocks, as peridotite, diabase, gabbro, norite, basalts, etc. Chrysolite (olivine) is a very brittle mineral and shows under mountain making pressure “cataclastic” structure. Chromite is a characteristic associated mineral. When not too poor in Fe, chrysolite becomes permanently red and pleochroic when strongly heated. Chrysolite is decomposed by hydrochloric and sulphuric acids, with separation of gelatinous silica. H., 6.5 to 7. Sp. gr., 3.3 to 3.4.

Hyalosiderite (a more ferruginous chrysolite) and _Fayalite_ ($Fe_{2}SiO_{4}$) may be reddish in sections, and common in the basic porphyritic eruptive rocks.

IOLITE, Cordierite, Dichroite.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: _■_ = a. ELONGATION ■ a′. $Mg_{3}(Al.Fe)_{6}Si_{8}O_{28}$.

■Usual Appearance in Sections■: Grains, more rarely crystals of short prismatic habit, which often form pseudo-hexagonal interpenetration twins. Crystals may have edges rounded or corroded. Colorless, but may be bluish. Index of refraction a little lower than quartz (_n′_ = 1.539, $\alpha = 1.535$, $\gamma = 1.544$), hence _relief_ low and surface smooth. Cleavage very variable, parallel to brachy pinacoid (010), especially noticeable when decomposition has taken place. Inclusions of sillimanite, zircon, rutile, etc., may be seen. Pleochroism usually not observed, but noticed in blue sections (yellowish white ■ _■_ to blue). Pleochroic halos (yellow) surrounding inclusions common, see p. 59.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha = 0.009$), like quartz. Interference colors middle first order, white to yellow. _Extinction_ in general parallel to cleavage cracks. In _convergent light_, Ax. pl. ■ (100), Bx_{_a_}. ■ _■_; axial angle large (hyperbolas only seen without ellipses) (2_E_ = 64° to 150°); optical character (–).

■Alteration■: Takes place readily, forming greenish mica-like decomposition products, the decomposition commencing along the crevices or about the inclusions.

■Distinguished from■: QUARTZ by observation in convergent light (quartz is uniaxial), decomposition and pleochroism or pleochroic halos. The section can also be treated with hydrofluosilicic acid, when the evaporated solution yields characteristic prismatic crystals of magnesium fluosilicate.

REMARKS: Found in gneiss, hornstone, granite, granulite, etc., and in some volcanic rocks. It is often associated with garnet, biotite, sillimanite, etc. In a thick section heating to redness makes the pleochroism more distinct. Iolite is only slightly acted on by acids. H., 7 to 7.5. Sp. gr., 2.6. It is hard to make a mechanical separation from quartz, on account of similarity in sp. gr.

NATROLITE.

ANISOTROPIC. BIAXIAL. ORTHORHOMBIC. COMPOSITION: _■_ = c. ELONGATION ■ c′. $Na_{2}Al_{2}Si_{2}O_{10} + 2H_{2}O$.

■Usual Appearance in Sections■: Aggregates of colorless, fibrous crystals, which may have sphærulitic structure, showing a dark cross between crossed nicols. Index of refraction lower than balsam (_n′_ = 1.483, $\alpha = 1.478$, $\gamma = 1.490$), hence (in large crystals) the surface would appear rather rough.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha = 0.012$). Interference colors the middle first order (yellow, etc.), a little higher than those of quartz. _Extinction_ parallel to fibres. Optical character (+).

REMARKS: Never a primary mineral in rocks, but found in igneous rocks filling amygdaloidal cavities, and also as a very common alteration product of sodalite, noselite, nephelite and acid plagioclases. It gelatinizes easily with hydrochloric acid. H., 5 to 5.5. Sp. gr., 2.2.

OTHER ZEOLITES.

COMPOSITION: Hydrous silicates; Al, Ca and Na being the chief bases.

■Usual Appearance in Sections■: The form depends on the individual mineral species, but the majority appear in elongated crystals or fibers. They are all colorless and most of them have a small index of refraction, hence no _relief_ (prehnite has distinct relief).

■Crossed Nicols■: The double refraction is generally very weak (between that of nephelite and quartz), giving very low order interference colors (prehnite and thomsonite have strong double refraction).

REMARKS: The zeolites are always secondary minerals in rocks. They gelatinize with hydrochloric acid.

GYPSUM.

ANISOTROPIC. BIAXIAL. MONOCLINIC. COMPOSITION: $CaSO_{4} + 2H_{2}O$.

■Usual Appearance in Sections■: Colorless grains or fibers. May be colored, however, by inclusions of carbonaceous matter, iron oxides, etc. Index of refraction about the same as orthoclase (_n′_ = 1.525, $\alpha = 1.521$, $\gamma = 1.531$), hence no _relief_ and surface smooth. Twinning lamellæ abundant. Cleavage parallel to (010) gives abundant cracks, other cleavages may also be noticed.

■Crossed Nicols■: Double refraction weak ($\gamma - \alpha = 0.010$), the same as quartz. Interference colors middle first order, white to yellow. _Extinction_ parallel to most perfect cleavage cracks in sections parallel to _b_ axis; large extinction angles noticed with reference to less perfect cleavages. In _convergent light_, Ax. pl. ■ (010), _i.e._, ■ to most distinct cleavages; Bx_{a}. (c) $\Lambda = 54°$ front; 2_E_ = 104°; optical character (+). As the characters of gypsum are not always very marked it may be necessary to employ micro-chemical tests.

REMARKS: Forms a rock by itself, often associated with rock salt. It also occurs as an alteration product of anhydrite. Gypsum is soluble in hydrochloric acid. H., 1.5 to 2. Sp. gr., 2.2 to 2.4.

MONOCLINIC PYROXENES, Augite, etc.

Including the monoclinic minerals of the Pyroxene Group, which show distinctly the characteristic cleavage parallel to an almost right-angled prism.

ANISOTROPIC. BIAXIAL. MONOCLINIC. ELONGATION ■ c′.[91]

COMPOSITION: $RSiO_{3}$, R = Ca, Mg, Mn, Fe, Al chiefly, with the Ca predominating over the Mg.

■Usual Appearance in Sections■: Both in crystals and more or less irregular grains, Figs. 4 and 12, the habit varying with the chemical composition as follows:

Diopside (Ca, Mg varieties), long columnar crystals and grains.

Augite (ditto, but containing also Al and Fe), short prismatic crystals and grains.

Diallage, granular or lamellar (|| (100)), may show fibrous structure ■ _■_.

Prism angle = 87° 06′ (important in cross-sections). Sections of crystals nearly at right angles to the vertical axis _■_ are octagonal or square with truncated corners, Figs. 4 and 53, while those parallel to the _■_ axis are lath-shaped. Pyroxene also occurs in skeleton crystals and acicular microlites in eruptive rocks.

[Illustration:

FIG. 52.—Augite, section parallel to _■_ axis showing prismatic cleavage, in leucite-basal. (From Cohen.)]

Zonal structure (especially in augites) may be marked by differences in color or extinction, and in some basalts the crystals have the “hour-glass” structure.

Twinning.—Common, usually the twinning plane being the ortho pinacoid (100). Twin lamellæ may be noticed. Intergrowths occur with orthorhombic pyroxene and amphibole.

Color.—From almost colorless through green (diopsides, Na pyroxenes, etc.) to brown (augites); the red to brownish-red color of certain augites has been considered due to manganese. Yellow color very rare.

Index of Refraction.—_n′_ = 1.68 to 1.72 (α = 1.671 to 1.706, γ = 1.700 to 1.728), hence _relief_ high and surface rough.

Cleavage.—More or less perfect parallel to prism of 87° 06′. Cleavage cracks distinct and numerous, but not generally running uninterruptedly through crystal, Figs. 12 and 52. Cleavage not so perfect as that of amphibole.

Parting.—Diallage and diopside have distinct parting parallel to ortho pinacoid (100), Fig. 53. Some crystals may show parting parallel to base (001).

Inclusions.—Tabular microscopic interpositions, similar to those in bronzite, may occur in diallage. The iron ores, apatite, etc., may occur in augite.

■Polarized Light■:

[Illustration:

FIG. 53.—Diallage, cross-section.]

Pleochroism.—Usually not noticed, and in general only appearing as different shades of the same color. In some cases (diallage, fassaite and Na rich augite) well marked, a and c green to yellowish green and b brownish to reddish-brown; hence pleochroism not intense in sections showing extinction angles. When Ti is present, violet parallel to _b_.

■_Crossed Nicols_■:

Double Refraction.—Strong ($\gamma - \alpha$ = 0.022 to 0.029), being stronger in the pale or colorless pyroxenes.

Interference Colors.—Second order, hence always bright tints.

Extinction.—Symmetrical in sections (through _b_ axis) showing intersecting cleavage lines, in such cases bisecting the angles of the cleavage. In sections showing parallel cleavage lines, only parallel in ortho pinacoid (100) sections, in all other sections an extinction angle being observed. The maximum extinction angle is large, lies in the obtuse angle, varies with the chemical composition from 36° 30′ to 54°, and is only obtained when the section of the crystal is parallel to the clino pinacoid (010), Fig. 54, varying from this angle to 0°, when the section is parallel to the ortho pinacoid (100). In Ti and Na pyroxenes the inclined dispersion is so great that extinctions are not sharp, but instead a change takes place in the interference color from bluish to brownish.

■_Convergent Light_■: Axial plane parallel to clino pinacoid (010). Fig. 54. A cleavage flake parallel to ortho pinacoid (100) shows the emergence of an optic axis (orthorhombic pyroxene parallel to best pinacoidal cleavage would not show figure). Bx_{_a_}.(c) Λ _■_ = 36° to 54° front. Axial angles large (2_E_ = 70° to 112°). Optical character (+). The interference figures are distinct on account of the strong double refraction.

■Alteration■: May take place to chlorite, serpentine or amphibole (uralitization[92]), depending on the chemical composition and the conditions producing the change.

[Illustration:

FIG. 54.—Diopside, clino pinacoid section.]

■Distinguished from■:

(_a_) ORTHORHOMBIC PYROXENES.—By extinction angle, the orthorhombic pyroxenes having always parallel or symmetrical extinction in sections parallel to _a_, _b_, or _c_, and by higher order interference colors. Also from hypersthene by absence of, or much fainter, pleochroism. Diallage and bronzite might be confused on account of pronounced pinacoidal parting, fibrous structure and inclusions; but may be distinguished by the presence or absence of extinction angles and also by the position of the optic axes relative to the best cleavage plates.

(_b_) AMPHIBOLE.—See under amphibole.

(_c_) EPIDOTE and CHRYSOLITE (Olivine). When light colored and granular, by examination in convergent light. The plane of the optic axes is parallel to the clino pinacoid (010), hence to the longitudinal axis and prismatic cleavage cracks, while in epidote it is at right angles to these directions and in chrysolite parallel to the base. Also yellow color is common in epidote but rare in pyroxene.

REMARKS: Next to the feldspars pryoxene is the most common constituent of the igneous rocks. Diopside and fassaite (green) are found in contact rocks; also, what appear to be the same pyroxenes, in many eruptive rocks, as andesites, monzonites, etc. Malacolite (light green) is found in amphibolites and eclogites, where it may be associated with a greenish amphibole (smaragdite). Diallage (bladed and twinned) occurs in gabbros and pyroxenites. Common augite (brown) is found in the remaining basic eruptive rocks. In the schists the pyroxene is colorless.

Finally augite occurs as a secondary product resulting from the “magmatic resorption” of hornblende and biotite.

Chemical corrosion and mechanical deformation may occur. The green and brown augites when heated to redness on platinum foil may become red in color. In general the pyroxenes are not attacked by acids. H., 5 to 6. Sp. gr., 3.3 to 3.5. The sp. gr. of the pyroxenes is considerably higher than that of the amphiboles of similar composition, hence mechanical separations are possible.

Acmite (_Ægirine_) (Na pyroxenes).—Occur in green or brown, elongated prismatic crystals, often not very transparent and with marked pleochroism (like amphibole). Zonal coloring is common. When zonally intergrown with pyroxene the outer zone is ægirine. The elongation is ■ a′ (distinction from amphibole whose elongation is ■ c′). The index of refraction is higher than in the other pyroxenes (_n′_ = 1.792, α = 1.763, γ = 1.813) and the double refraction stronger ($\gamma - \alpha$ = 0.050). The _extinction_ angle is small (5°) and the optical character (—).

The term _Ægirine-augite_ may be used to describe a soda, pleochroic augite with a large extinction angle.

These pyroxenes are only found in the eruptive rocks rich in alkalies, as elæolite-syenite, phonolite, certain trachytes, etc.; hence are associated with elæolite, sodalite, leucite, etc. The small, second generation, crystals, in the ground mass of a rock, are always the richest in Na of the pyroxenes in that rock.

AMPHIBOLE, Hornblende, etc.

ANISOTROPIC. BIAXIAL. MONOCLINIC. ELONGATION ■ c′.

COMPOSITION: $RSiO_{3}$. R = Mg, Ca, Fe chiefly also may contain Al, Na, Mn. The Mg predominates over the Ca.

[Illustration:

FIG. 55.—Hornblende, showing twinning between crossed nicols, in amphibole-biotite-granite. (From Cohen.)]

■Usual Appearance in Sections■: Both in crystals and more or less irregular grains, often fibrous, Figs. 55 and 56, the habit varying with the chemical composition as follows:

Tremolite ($Mg_{3}Ca$) and _Actinolite_ ($(MgFe)_{3}Ca$ varieties), in long columnar to needle-like individuals, with no terminal planes or with frayed out ends. May be in dense aggregates.

Pargasite in well developed crystals.

Common green Hornblende (aluminous varieties) in crystals, compact grains or shreds.

Basaltic Hornblende (iron rich, aluminous varieties) in prismatic crystals of varying length, which may often show “magmatic resorption” (to augite and magnetite) around outer zone or throughout whole crystal.

[Illustration:

FIG. 56.—Hornblende, section parallel to _■_ axis, showing prismatic cleavage, in hornblende-diorite. (From Cohen.)]

Crystals are simple in form of prismatic habit, with prism angle 124° 30′. Cross-sections are acutely rhombic, generally with acute angles truncated, hence six-sided (pyroxene being eight-sided). Longitudinal sections are lath-shaped and fibrous structure may be noticed. Skeleton crystals may also occur, being very fine in certain pitchstones.

Zonal structure and parallel growth may be noticed in the amphiboles.

Twinning.—Frequent, parallel to ortho pinacoid (100). Twins dual, less often multiple, Fig. 55. Intergrowths with pyroxene and biotite occur.

Color.—From colorless (tremolite), through green (actinolite, pargasite and hornblende) to brown (basaltic hornblende). Yellow in some varieties and bluish in the soda varieties.

Index of Refraction.—_n′_ = 1.621 to 1.641 (α = 1.607 to 1.629, γ = 1.634 to 1.653) (1.719, in the basaltic hornblende), hence _relief_ distinct and surface rough.

Cleavage.—Perfect, parallel to prism of 124° 30′. Generally appears in thin sections as sharp cracks crowded close together, Figs. 56 and 57. More perfect than in pyroxene.

Some of the long prisms (actinolite and tremolite) may show transverse parting.

Inclusions.—The iron ores, apatite, etc., may be found in hornblende.

[Illustration:

FIG. 57.—Hornblende, cross-section.]

■Polarized Light■:

Pleochroism.—All colored amphiboles show pleochroism, which in general is stronger the darker the color of the variety (actinolite and pargasite show but little). The absorption is very marked in the hornblendes, being greatest in the general direction of the cleavage lines in longitudinal sections. Marked differences in absorption are also characteristic of the mineral species biotite, tourmaline and allanite. Pleochroic halos (brownish) surrounding inclusions may be noticed.

■Crossed Nicols■:

Double Refraction.—Quite strong, but a little weaker than in pyroxene (γ-α = 0.019 to 0.027). Ferruginous basaltic hornblende has strong double refraction (γ-α = 0.072).

[Illustration:

FIG. 58.—Actinolite, clino pinacoid section.]

Interference Colors.—Second order, hence bright tints, but in darker colored varieties not so noticeable as in pyroxenes, due to the stronger absorption of parts of the light. The colors of basaltic hornblende are so high that they show no bright tints.

Extinction.—Always symmetrical in sections (through _b_ axis) showing intersecting cleavage lines, in such cases bisecting the angles of the cleavage. In sections showing parallel cleavage lines, only parallel in ortho pinacoid (100) sections, in all other sections an extinction angle being observed. The maximum extinction angle lies in the acute angle and is much smaller than in pyroxene, varying with the chemical composition from 0°–20°. In hornblende, actinolite and tremolite 12°–20°, Fig. 58; in the basaltic hornblende 0°–10°. The maximum extinction angle is only obtained when the section of the crystal is parallel to the clino pinacoid (010), varying from this angle to 0°, when the section is parallel to the ortho pinacoid (100).

■Convergent Light■: Axial plane parallel to clino pinacoid (110), Fig. 58. Bx_{_o·_}(c) ∧ _■_ = 0°–20° behind. Axial angles large (2_E_ = 77° to >180°). Optical character (–). Pargasite is (+).

■Alteration■: May take place to chlorite, talc, serpentine, asbestus, etc., depending on the chemical composition. Amphibole frays out and becomes fibrous during alteration, and may also lose color.

■Distinguished from■:

(_a_) PYROXENE.—By usually much stronger pleochroism in the colored varieties, and by cleavage and extinction angle. In pyroxene the cleavage (parallel to prism of 87° 06′) is less perfect; and the extinction angle is much larger, varying from 36° to 54°.

(_b_) BIOTITE.—By the extinction in the mica being always about parallel to the cleavage. Both have strong absorption, but biotite shows very slight pleochroism in sections parallel to the cleavage, and has only the one cleavage parallel to the base. Also the biotite has lower index of refraction and generally shows uniaxial interference figure.

Colorless tremolite may be distinguished from muscovite and talc by extinction angles, relief and lower order interference colors.

(_c_) TOURMALINE.—By presence of cleavage, and by the fact that absorption is most marked about parallel to the elongation (also parallel to cleavage lines), while in tourmaline the absorption is strongest at right angles to the elongation.

(_d_) The ORTHORHOMBIC PYROXENES.—By extinction angles, the latter having parallel extinction in all sections parallel to _a_, _b_ and _c_, and by prismatic cleavage of 124° 30′. Pleochroism is strong in the colored varieties of both species, but in amphibole it appears more generally as a variation of the same color; while in hypersthene a change in color is often noticed, from brownish-red to greenish parallel to _■_ axis.

(_e_) SILLIMANITE and CYANITE.—See under the latter.

REMARKS: Amphibole comes next to pyroxene in importance and distribution of the dark colored ferruginous rock-forming minerals. As a rule it occurs in rocks with a large percentage of SiO_{2}, associated with quartz and orthoclase; while augite generally occurs in rocks of a basic nature, associated with plagioclase and little or no free SiO_{2}. Furthermore amphibole contains hydroxyl and is therefore naturally found in the deep eruptive rocks; its place being taken by augite in the effusives. By application of heat hornblende changes to augite, while hydrochemical processes bring about the opposite result “uralitization.”

Tremolite and actinolite are found in contact rocks and crystalline schists, also as a result of the alteration of olivine into serpentine. Pargasite occurs in contact rocks. Common green hornblende is found in the plutonic rocks (Na poor and SiO_{2} rich), also in contact rocks and crystalline schists (amphibolites). Brown hornblende replaces the green variety in the basic plutonic rocks. Basaltic hornblende is found in many effusive rocks.

The hornblende crystals in eruptive rocks, being among the first formed constituents, have often suffered subsequent corrosion by the magma, giving rise to the dark border already mentioned. The brown primary hornblende in some rocks may be changed by a process analogous to “uralitization” into a green, reed-like hornblende. Mechanical deformations are found in massive and schistose rocks. Light green amphiboles, with weak pleochroism, may often be colored intensely reddish-brown and made strongly pleochroic by heating to redness on platinum foil. In general the amphiboles are not affected by acids. H., 5 to 6. Sp. gr., 2.9 to 3.3.

Glaucophane, _Arfvedsonite_, etc. (Na rich amphiboles).—Occur blue to bluish-green in color, with pleochroism and weaker double refraction than the other amphiboles. Extinction angles vary from 4°–6° (glaucophane) to 14° (arfvedsonite). They are found in contact rocks, crystalline schists, eclogite, etc.

For the rarer and less known members of the amphibole group, resource should be had to more elaborate works.

Uralite.—Pyroxene altered to amphibole, having the outward crystal form of pyroxene and the physical characters and cleavage of amphibole. The change usually commences on the surface and the uralite does not form a single compact crystal, but consists of numerous slender columns parallel to one another. These little columns or fibers have their _c_ and [_=b_] axes parallel to the positions of these axes in the parent mineral. The color is green and the pleochroism weak to strong.

This change is called “_uralitization_” and results from hydrochemical processes. When the alteration is not complete, portions of the original pyroxene may be left, having all the characteristic optical properties of this latter mineral.

Anthophyllite, the orthorhombic amphibole, with always parallel extinction, is sometimes found in colorless to brownish, blade- to rod-like aggregates in crystalline schists and serpentine.

MICA GROUP.

ANISOTROPIC. BIAXIAL. MONOCLINIC. May appear hexagonal or orthorhombic. COMPOSITION: ELONGATION (■ cleavage) ■ c′.

Biotite (black or ferro-magnesium mica) = (H.K)_{2}(Mg.Fe)_{2}Al_{2}(SiO_{4})_{3}, approx.

Phlogopite = a magnesium mica, near biotite, but containing little Fe.

[Illustration:

FIG. 59.—Mica. _A_, biotite, showing hexagonal cross-section and zonal markings. _Minette_, Freiburg. _B_, Biotite, showing strong absorption parallel to cleavage and also zonal marking (_P_ = plane of vibration of polarizer). _Minette_, Cumberland. _C_, Muscovite in bent shreds in gneiss.]

Muscovite (white or potash mica) = H_{2}(K.Na)Al_{3}(SiO_{4})_{3}, with some replacement by Mg or Fe.

■Usual Appearance in Sections■: Scales, which may be notched or jagged, with lateral sections lath-shaped; or shreds, Fig. 59 C. When distinctly crystallized (magnesium micas) the thin hexagonal plates have plane angles of 120°, Fig. 59 A. Phlogopite crystals may be extended in direction of _■_ axis.

Zonal structure not uncommon in the magnesium micas, Fig. 59 A, which may also have dark iron ore border like hornblende.

Twinning.—Common, generally parallel to base; seen in sections showing cleavage by variations in extinction, in basal sections by distorted interference figures.

Micas of different kinds often associated together in parallel position, also intergrown with hornblende, pyroxene, chlorite and quartz.

Color.—Depends on chemical composition. Biotites, brown, green or red to almost opaque. Phlogopites, colorless or yellowish. Muscovites colorless.

Index of Refraction.—_n′_ = 1.564 to 1.619 (α = 1.541 to 1.580, γ = 1.575 to 1.638), hence somewhat marked _relief_ and surface varies in appearance from slightly rough to fairly rough. In polarized light the surface appears roughest when the cleavage cracks are parallel to the plane of the polarizer.

Biotite has more marked relief.

Cleavage.—Very perfect, parallel to base (001), Fig. 60. Basal sections show no cleavage, but all other sections show many sharp, parallel cleavage cracks.

[Illustration:

FIG. 60.—Biotite, showing basal cleavage, in biotite-granite. (From Cohen).]

For percussion and pressure figures, see reference given below.[93]

Inclusions.—May be arranged parallel to lines of pressure figure. Rutile needles, tourmaline, apatite, etc., common in magnesium mica. Zircon inclusions often surrounded by pleochroic halos.

■Polarized Light■:

Pleochroism.—Varies with the color, being very marked in the colored varieties (from pale yellow to chestnut-brown or black). The strong absorption, about parallel to the cleavage lines, is very characteristic of the colored mica, Fig. 59 B. Strong absorption is also noticed in hornblende, tourmaline and allanite. Absorption may even be noticed around inclusions (pleochroic halos) in colorless, non-pleochroic micas. Cleavage plates of biotite are not pleochroic unless the axial angle is large.

■Crossed Nicols■:

Double Refraction.—Very strong ($\gamma - \alpha$ = 0.034 to 0.058).

Interference Colors.—High order (third). May be very bright in thin sections of the colorless micas, and at times be so high in order as not to show any marked color tints. May not be noticeable in sections of the colored varieties, due to absorption of parts of the light.

Extinction.—About parallel to cleavage lines. Very small extinction angles may be noticed in biotites. Basal sections of biotite (the approximately hexagonal mica) usually appear isotropic.

Mottled appearance (like “Birds-eye” maple) characteristic, caused by distortion of the flexible laminæ during grinding. Most noticeable in sections inclined to cleavage and near position of extinction.

■Convergent Light■: Axial plane[94] and Bx_{_a_}, practically at right angles to basal cleavage; therefore cleavage plates always show well defined interference figures, generally biaxial in character. The axial angles vary greatly, being usually small for biotite and phlogopite (may appear uniaxial) and large for muscovite (2_E_ = 55° to 90°). Optical character for all micas (–).

■Alteration■: Biotites decompose quite easily, lose color and may become completely bleached, which appears to be due to a leaching out of the iron. May also alter to green chlorite, with a fraying out of the mica and a change to chloritic structure.

Phlogopites may alter to fibrous, scaly masses, apparently chiefly talc. “Sagenite” webs of rutile may accompany the alteration.

Muscovites are characterized by their freshness, and do not seem to suffer from weathering.

■Distinguished from■:

(_a_) HORNBLENDE.—Magnesium mica has extinction about parallel to the cleavage, while hornblende may have extinction angles of from 0° to 20°. Both have strong absorption, but biotite shows very slight pleochroism in basal sections, which also give approximately uniaxial interference figures in convergent light.

(_b_) TOURMALINE.—Magnesium mica shreds show absorption parallel to elongation, while in tourmaline the absorption is at right angles to elongation. There is also an absence of cleavage in tourmaline.

(_c_) CHLORITE.—By strong double refraction, the very high order colors, however, being often not noticed. Chlorite also shows aggregate structure and is almost always greenish in color.

(_d_) TALC.—White mica by large axial angle of scales in convergent light and by micro-chemical tests. The distinction may be very difficult.

REMARKS: Muscovite is a rare primary mineral in eruptive rocks, except in two-mica granite, etc. As a secondary mineral it occurs in dense scaly aggregates or as pseudomorphs after feldspar, nephelite, etc. It is frequent in crystalline schists and is probably also the mica in amphibolite and eclogite. Phlogopite is found chiefly in contact metamorphic limestone; and may be distinguished from muscovite by nearly uniaxial character and less sharp cleavage. Biotite is much more widely distributed, occurring especially in eruptive rocks, crystalline schists and contact rocks.

Chemical corrosion occurs in original biotite of porphyritic rocks, producing a “resorption border” of augite and magnetite. Mechanical deformations, producing bending and slipping along “gliding” planes (oblique to cleavage), are common to all varieties of mica and may produce change to chlorite. The muscovites, together with the feldspars, are the most characteristic minerals of dynamo metamorphic origin. Biotites and phlogopites are attacked by sulphuric acid at high temperatures. Muscovite is but slightly attacked by acids. H., 2 to 3. Sp. gr., 2.7 to 3.2. The specific gravity separation between the micas is difficult on account of the scaly nature of the minerals.

Other micas occur, some being alteration products of those already described. Among these may be mentioned:

Lithia Mica.—Both light and dark colored, occurring in granitic rocks and often only distinguished chemically from muscovite and biotite.

Damourite (_Sericite_) (hydrous K mica).—A secondary product usually in colorless, fine scaly aggregates in phillites, sericite-schists, etc.

CHLORITE GROUP.

Embracing the members of the Chlorite Group, commonly occurring in rocks.

ANISOTROPIC. BIAXIAL. MONOCLINIC.

The minerals of this group usually appear uniaxial, and crystallize in part with hexagonal symmetry.

COMPOSITION: May be considered as isomorphous mixtures of $H_{4}(MgFe)_{3}Si_{2}O_{9}$ and $H_{4}(MgFe)_{2}(AlFe)_{2}SiO_{9}$ (Rosenbusch).

■Usual Appearance in Sections■: Minute, scaly aggregates, which may incline to radial grouping; or in minute grains as a pigment (veridite) in other minerals.

Twinning.—May be seen as in mica.

Color.—Generally green, varying from greenish white to dark green, rarely colorless or red.

Index of Refraction.—n' = 1.567 to 1.589 (α = 1.560 to 1.585, γ = 1.571 to 1.596), hence no marked relief and only slightly rough surface.

Cleavage.—Like mica, very perfect; parallel to flat face, which is considered to be the basal plane. This cleavage may not be noticed, especially in secondary chlorite in rocks.

■Polarized Light■:

Pleochroism.—In green and yellow tints (green ■ cleavage), being more marked in dark colored varieties. Basal sections are non-pleochroic, the mineral being practically uniaxial. Pleochroic halos may be seen.

■Crossed Nicols■:

Double Refraction.—Generally very weak ($\gamma - \alpha$ = 0.001 to 0.011).

Interference Colors.—Very low first order, gray or white, at times scarcely noticed. Anomalous colors, however, often seen (deep blue or brown.)

Extinction.—Plates parallel to cleavage generally appear isotropic or only show faint color. In other sections extinction is apparently parallel to the cleavage in the uniaxial type, but extinction angles may be noticed when type is biaxial. Complete extinction may not be noticed, due to aggregate structure.

■Convergent Light■: Plates parallel to cleavage show, at times, an indistinct interference cross, which may open into two hyperbolas, indicating biaxial nature of crystallization. Ax. pl. ■ (010); Bx_{_a_}. Λ _■_ = 0° to 15°; 2_E_ variable. Optical character (±).

■Distinguished from■: SERPENTINE.—By general green color (serpentine, with exception of Fe rich variety, is colorless), pleochroism and frequent anomalous interference colors; but the distinction between these two minerals may be very difficult. Chlorite may resemble decomposed or green mica (mica has, however, strong double refraction). The different species in the chlorite group cannot usually be distinguished in rocks.

REMARKS: The chlorites are essentially secondary minerals, derived from the aluminous silicates, biotite, augite, garnet, feldspar, etc. They are found abundantly in chlorite-schists, contact rocks, etc., and as pigment (veridite) in altered eruptive rocks. May occur as a primary constituent of eruptive rocks, often in parallel growth with biotite. Chlorides are acted on by hot hydrochloric acid, and decomposed easily by sulphuric acid. H., 2 to 3. Sp. gr., 2.6 to 2.96. A thin section heated to redness on platinum foil loses water and becomes opaque. Ferruginous varieties are turned reddish-brown to black by heating (serpentine, as it contains less iron, may give negative results with this test).

Delessite.—Found in sphærulites, filling cavities in amygdaloidal basic rocks, and in pseudomorphs. It appears to be much altered to other minerals.

TALC.

ANISOTROPIC. MONOCLINIC (Pseudo-Hexagonal). COMPOSITION: ELONGATION ■ c′. $H_{2}Mg_{3}(SiO_{3})_{4}$.

■Usual Appearance in Sections■: In fine scaly, colorless aggregates. Sections, cutting across the scales, would show rod-like forms. Index of refraction only a little higher than balsam (_n′_ = 1.572, α = 1.539, γ = 1.589), hence no marked _relief_ and only slightly rough surface. Cleavage perfect parallel to base, like mica.

■Crossed Nicols■: Double refraction very strong ($\gamma - \alpha$ = 0.050). Interference colors third order, like muscovite. _Extinction_ parallel to basal cleavage lines. In _convergent light_, Ax. pl. ■ (100), Bx_{a}. ■ _■_; axial angle small (2_E_ = small); optical character (–).

■Distinguished from■: MUSCOVITE (with which it is easily confused) by micro-chemical tests, proving absence of alkalies and Al; and often by the more aggregate structure of the talc. Also by smaller axial angle of scales in convergent light.

REMARKS: Found mainly in metamorphic schists, etc., always as a secondary product. It is insoluble in hydrochloric acid. H., 1 to 1.5. Sp. gr., 2.6 to 2.8.

EPIDOTE.

ANISOTROPIC. BIAXIAL. MONOCLINIC. ELONGATION ■ a′ or c′.

COMPOSITION: $Ca_{2}Al_{2}(AlOH)(SiO_{4})_{3}$, with some Fe replacing Al.

■Usual Appearance in Sections■: Columnar to thick tabular crystals, more or less elongated parallel to ortho axis [_=b_], Fig. 61, or in granular aggregates.

[Illustration:

Epidote.

FIG. 61. FIG. 62. Ortho pinacoid section. Clino pinacoid section.]

Twinning.—May occur but rarely noticed. Irregular interpenetrations common with other members of the group; also parallel growths.

Color.—Colorless to yellowish (Fe poor) or yellow to greenish to yellow-brown (Fe rich).

Index of Refraction.—_n′_ = 1.751 but may be lower (α = 1.731, γ = 1.768), hence _relief_ high and surface rough.

Cleavage.—Parallel to base (001), Figs. 61 and 62, imperfect parallel to ortho pinacoid (100). Basal cleavage cracks not very numerous and appear parallel to general direction of elongation.

■Polarized light■:

Pleochroism.—Varies with the color, being faint in the light colored varieties, but strong when the color is marked (Fe rich).

■Crossed Nicols■:

Double Refraction.—Variable, often very strong ($\gamma - \alpha$ = 0.037).

Interference Colors.—Variable, often high (third) orders. Intergrowths with other members of the group are clearly shown by the “flecked” interference colors.

Extinction.—Parallel to cleavage in sections parallel to [_=b_] axis. In other sections extinction angles vary, see Fig. 62.

■Convergent Light■: Axial plane ■ (010), _i. e._, at right angles to the elongation of crystal and cleavage cracks, Fig. 61. Bx_{a}.}-(a) Λ _■_= 3° behind. Basal cleavage flakes show the almost ■ emergence of an optic axis. Axial angles very large (2_E_ > 180°). Optical character (–).

■Alteration■: Does not take place readily.

■Distinguished from■: Light colored MONOCLINIC PYROXENE.—By having plane of optic axes at right angles to cleavage cracks and direction of elongation; while in pyroxene plane of optic axes is parallel to parallel prismatic cleavage cracks or bisects the angle between intersecting cracks. Furthermore the yellow color is rare in pyroxene.

REMARKS: Epidote is essentially a secondary mineral, resulting from the alteration of the feldspars and the ferro-magnesium silicates. It is found in crystalline schists (especially those containing hornblende), gneiss, gabbro, diorite, diabase, lime-silicate hornstones, contact rocks, etc. Epidote is partially decomposed by hydrochloric acid. The Fe rich epidote can be changed to an intense color by “glowing” in the air. H., 6 to 7. Sp. gr., 3.32 to 3.45.

Piedmontite (containing Mn).—Red in color. Very pleochroic, red to yellow. Found in crystalline schists, the porphyrite of Scotland, the famous “Porfido rosso antico” of Egypt and in certain Japanese mica schists.

ZOISITE.

Essentially orthorhombic? members of Epidote group.[95]

COMPOSITION: Like epidote but without any Fe.

■Usual Appearance in Sections■: Similar to epidote or in columnar aggregates. Often intergrown with epidote.

Distinguished from epidote by general absence of color (colorless to yellowish) and pleochroism; by slightly lower refractive index (_n′_ = 1.699 to 1.720) and by much weaker double refraction ($\gamma - \alpha$ = 0.005 and less). The interference colors are very low order, gray to white, but anomalous colors are often seen (yellow or prussian blue). Extinction is in general parallel to pinacoidal cleavage cracks (except in clinozoisite).

The plane of the optic axes may be parallel or at right angles to cleavage cracks, and the optical character is (+).

REMARKS: Generally a secondary mineral. Found in crystalline schists, amphibolites, contact rocks, eclogite, etc., and in “saussurite.” May be hard to distinguish from vesuvianite and apatite.

ALLANITE, Orthite.

Monoclinic member of Epidote group.

COMPOSITION: Like epidote but containing cerium.

■Usual Appearance in Sections■: Similar to epidote in form; but distinguished by brown color (may be also almost colorless), strong pleochroism and absorption, and medium to weak double refraction ($\gamma - \alpha$ = 0.002 to 0.030). Lamellar twinning clearly seen on account of oblique extinction. When included in hornblende and mica it is surrounded by pleochroic halos. _n′_ = 1.78 about. Optical character (±). Usually perfectly fresh.

REMARKS: Found as an accessory mineral in SiO_{2} rich eruptive rocks and connected crystalline schists, and (light colored) in amphibolite and eclogite.

TITANITE, Sphene.

ANISOTROPIC. BIAXIAL. MONOCLINIC. COMPOSITION: $CaTiSiO_{5}$. ELONGATION ■ a′.[96]

■Usual Appearance in Sections■: Wedge-shaped crystals (in Na rich rocks, more prismatically developed); grains, which may be elongated; and aggregates of small rounded particles, which appear nearly opaque. Sections of crystals commonly acute rhombs, Fig. 63.

Twinning.—Occurs, the twinning boundary bisecting the acute angles of the rhomb (only noticed between crossed nicols), Fig. 64.

Color.—Reddish-brown to yellowish to colorless.

[Illustration:

FIG. 63.—Titanite, showing acute rhombic cross-section.]

Index of Refraction.—_n′_ = 1.920 to 1.963 (α = 1.888 to 1.913, γ = 1.978 to 2.054), hence _relief_ very marked and surface very rough.

Cleavage.—Imperfect and not parallel to predominant form, hence only appears as a few rough cracks, which are not parallel to any crystallographic boundary, Fig. 63. Cleavage rarely observed in secondary grains.

■Polarized Light■:

Pleochroism.—Varies with the color, being more distinct in colored crystals, yellowish (the lighter color) ■ a′ and reddish-brown ■ c′. Scarcely noticed when the color is light.

■Crossed Nicols■:

Double Refraction.—Very strong ($\gamma - \alpha$ = 0.090 to 0.141).

[Illustration:

FIG. 64.—Titanite, showing twinning in nepheline-syenite. (From Cohen.)]

Interference Colors.—Very high order, like those of calcite. Due to the fact that the refractive indices of two of the rays are very nearly alike, some sections may show very low order colors.

Extinction.—Extinction angles not characteristic. There may be no complete extinction in white light, owing to dispersion.

■Convergent Light■: On account of the very strong characteristic dispersion of the optic axes ($\rho > \nu$), the axial angle varies a good deal with the color of the light used, (St. Gotthard) 2_E_{IA}_ = 57°, 2_E_{Tl}_ = 47°. By using colored glasses this variation in the axial angle can be seen. The axial plane lies in the clino pinacoid (010), hence bisects the obtuse angle in the rhombic cross-section, Fig. 63. Bx_{_a_}.(c) Λ _■_ = 51° front. The optical character is (+).

■Alteration■: May take place.

■Distinguished from■:

(_a_) STAUROLITE.—In convergent light the axial plane is shown to be in the shorter diagonal of the rhombic cross-section, while in staurolite it is in the longer diagonal.

(_b_) RUTILE.—By biaxial character.

(_c_) CALCITE.—The light colored titanite (sphene), in absence of twinning, by higher index of refraction.

Titanite may easily be confused with some of the rarer minerals.

REMARKS: Titanite is always an accessory mineral and is found distributed in all rocks, except SiO_2 rich eruptive and magnesia silicate rocks. As a secondary mineral it forms rims around other titanium minerals or pseudomorphs after them and also the principal part of _leucoxene_. It is partly soluble in hot hydrochloric acid and completely decomposed by sulphuric acid. H., 5 to 5.5. Sp. gr., 3.3 to 3.7. In a specific gravity separation it falls with the ferruginous minerals (on account of its density) and from these can generally be separated by electromagnetic methods.

FELDSPAR GROUP. Orthoclase, Microcline and the Plagioclases.

ORTHOCLASE.

ANISOTROPIC. BIAXIAL. MONOCLINIC. ELONGATION (■ cleavage) ■ a′.

COMPOSITION: $KAlSi_3O_8$, with some replacement by Na.

■Usual Appearance in Sections■: In crystals and grains. In porphyritic rocks habit of crystals more or less tabular parallel to clino pinacoid (010), or rectangular much extended parallel to clino axis _à_, with cross-sections six-sided, or rectangular to long lath shape, Figs. 65 and 66. Crystals may be changed into rounded or looped grains by chemical corrosion, Fig. 6. Adularia crystals

more prismatically developed, giving rhombic sections. Dimensions of crystals vary extremely; microlites occur, at times forming sphærulitic structure. The very fine grained ground-mass “microfelsite” (not resolved by the microscope) consists largely of feldspar.

[Illustration:

Orthoclase cleavage plates.

FIG. 65.—Basal. FIG. 66.—Clino pinacoid.]

Intergrowths with microcline and plagioclase common, forming “microperthite” when lamellæ are microscopic. May be in zonal formation with plagioclase (the orthoclase on the periphery). Also intergrown with quartz[97] forming “pegmatite” and “micro-pegmatite,” Fig. 67.

[Illustration:

FIG. 67.—Micro-pegmatitic structure, in granophyric quartz-porphyry. (From Cohen.)]

Zonal structure often seen, Fig. 20, especially when decomposition has commenced; and in fresh crystals may be indicated by zonal arrangement of inclusions.

Twinning.—Very common, generally after _Carlsbad_ law, Figs. 18 and 69; the twinning boundary, dividing the section longitudinally, either being parallel to edges of crystal or bent or jagged. Twinning after _Baveno_ (twinning boundary diagonal, with the two parts extinguishing at the same time, but having a and c directions crossed in the two portions) and _Manebach_ laws less common.[98]

[Illustration:

FIG. 68.—Orthoclase, ortho pinacoid section showing cleavages intersecting at 90°, in augite-syenite.]

Color.—Colorless or tinged by oxide of iron. Cloudy if decomposed.

Index of Refraction.—_n′_ = 1.523 (α = 1.519, γ = 1.526), hence no _relief_ and surface smooth.

Cleavage.—Varies and sometimes only seen in very thin sections, but is an important character and should always be searched for. It occurs perfect, parallel to base (001), and almost as perfect parallel to clino pinacoid (010). The two cleavages intersect at 90° in section parallel to the [_=b_] axis, Fig. 68.

Inclusions.—May be present and arranged in regular or zonal order, but not important. Do not occur in individuals of a second generation.

■Polarized Light■:

Pleochroism.—None.

■Crossed Nicols■:

Double Refraction.—Very weak ($\gamma - \alpha$ = 0.007).

Interference Colors.—Lower first order, gray, white, etc., not quite so bright as colors of quartz and plagioclase.

Extinction.—Being monoclinic the extinction angle on base (001), with reference to clino pinacoid (010) cleavage cracks, is 0°. On clino pinacoid with reference to basal cleavage cracks, it is 5°. Some sections (notably in glassy sanidine grains) may appear dark during complete rotation. This is due to the fact that the axial angle is very small and the sections act approximately like those of a uniaxial mineral at right angles to the optic axis.

■Convergent Light■:[99] Plane of optic axes in general at right angles to clino pinacoid (010) (plane of symmetry), Fig. 65, hence parallel to trace of basal cleavage; but in some sanidines parallel to plane of symmetry. Bx_{_a_} (a) Λ _a_ = 5° above. Axial angles vary, 2_E_ = 125° (orthoclase), 0°–50° (sanidine).[100] May appear uniaxial when axial angle is very small. Optical character (–).

■Alteration■: Very common to clay,[101] muscovite, hydrargillite, etc. Generally commences along the cleavage cracks, and when it has progressed very far the whole feldspar appears opaque or cloudy, and no perceptible change may take place between crossed nicols. As decomposition is very prevalent in many rocks, the orthoclase is rarely clear or pellucid. Epidote is often formed when accessory solutions are present.

■Distinguished from■:

(_a_) The other FELDSPARS and MELILITE.—See under the latter minerals.

(_b_) QUARTZ.—Feldspar is biaxial but when occurring in clear glassy grains (notably sanidine), which appear uniaxial in convergent light, may resemble quartz. When tested the optical character is (–), while that of quartz is (+).

REMARKS: The members of the feldspar group are the widest distributed of the rock-forming minerals and their recognition is of the utmost importance on account of their bearing on the systematic classification of rocks. Orthoclase is found as an essential constituent in the more acid plutonic and older volcanic rocks, as granite, syenite, trachyte, porphyry, and also in gneiss, crystalline schists, more seldom in contact rocks and subordinate in clastic rocks.

Chemical corrosion (producing rounded or looped grains), Fig. 6, and mechanical deformation (producing angular, sharp-edged, broken grains, bending and undulatory extinction[102]), Fig. 7, occur in orthoclase. When a rock containing feldspar crystals is shattered, the orthoclase breaks parallel to basal cleavage and plagioclase parallel to twinning plane. Orthoclase is practically insoluble in acids. H., 6 to 6.5. Sp. gr., 2.56.

[Illustration:

FIG. 69. —Sanidine, showing Carlsbad twin and cross-parting, in nepheline-phonolite. (From Cohen.)]

Sanidine.—This clear, glassy variety of orthoclase occurs in the later eruptive rocks, rhyolite, trachyte, obsidian, etc. Sanidine often has a parting parallel to ortho pinacoid (100), which may be noticed in sections so thick that the cleavage is not seen, Fig. 69. In general it shows no sign of decomposition, and has a smaller axial angle than orthoclase. Inclusions of glass are more abundant than in orthoclase.

MICROCLINE.

ANISOTROPIC. BIAXIAL. TRICLINIC. COMPOSITION: $KAlSi_3O_8$.

■Usual Appearance in Sections■: As a rock constituent in irregular grains.

In general characters like orthoclase and _distinguished_ from it and the plagioclases by characteristic “_gridiron_” structure between crossed nicols, resulting from the polysynthetic twinning after both _Albite_ and _Pericline_ laws, Fig. 19. This crossed twinning will show in all sections except those parallel to the brachy pinacoid (010). The lamellæ are generally thinner than in the plagioclases and more “spindle-shaped.”[103]

Furthermore the rather obscure triclinic crystallization is shown by an extinction angle of + 15° on basal cleavage plates with reference to brachy pinacoid (010) cleavage lines (distinction from orthoclase, which has O° extinction angle).

REMARKS: Found with orthoclase, often almost replacing it, in granite, syenite, gneiss, etc., and is one of the last minerals to form. It is notably resistant to decomposition. A structure like the microcline twin structure may be produced in orthoclase by dynamic action.[104]

THE PLAGIOCLASES. Albite, Oligoclase, Labradorite, Anorthite.

ANISOTROPIC. BIAXIAL. TRICLINIC.

ELONGATION (■ Albite twin lamellæ) ■ a′ (except in anorthite when it may be ■ a′ or c′).

COMPOSITION:[105]

Albite, $NaAlSi_3O_8$.

Oligoclase, _n_(NaAlSi_{3}O_{8}) + CaAl_{2}Si_{2}O_{8}, or _n_ Ab + An, _n_ = 2 to 6.

Labradorite, NaAlSi_{3}O_{8} + _n_(CaAl_{2}Si_{2}O_{8}), or Ab + _n_ An, _n_ = 1, 2 or 3.

Anorthite, CaAl_{2}Si_{2}O_{8}.

■Usual Appearance in Sections■: Much the same as orthoclase. Lath-shaped[106] forms and microlites very common, especially in the acid series.

[Illustration:

FIG. 70.—Plagioclase, showing narrow lamellæ, in diabase. (From Cohen.)]

[Illustration:

FIG. 71.—Plagioclase, showing broad lamellæ, in gabbro. (From Cohen.)]

Twinning.—Polysynthetic, after _Albite_ law, almost universal; the twinning appearing between crossed nicols as a series of dark and light bands, bounded by parallel edges, Figs. 70 and 71. The twin lamellæ are parallel to brachy pinacoid (010), hence not observed in sections parallel to this pinacoid. The lamellæ may appear irregular and interrupted, and seem to be broader in the basic than in the acid series. When this twinning fails, however, as in the basic plagioclases in certain metamorphic rocks, the determination becomes very difficult. In some cases polysynthetic twinning, after both _Albite_ and _Pericline_ laws, may take place at the same time, giving rise to a structure somewhat similar to that of microcline, Fig. 72. In addition the polysynthetic crystals may be twinned like orthoclase after _Carlsbad_ and _Baveno_ laws.

The general characters are the same as in orthoclase with the following differences:

Indices of Refraction: _n′_ = 1.535 (α = 1.532, γ = 1.540) Albite. _n′_ = 1.541 (α = 1.537, γ = 1.545) Oligoclase, Ab_{4}An_{1}. _n′_ = 1.559 (α = 1.555. γ = 1.563) Labradorite, Ab_{1}An_{1}. _n′_ = 1.582 (α = 1.575, γ = 1.588) Anorthite.

The surface of anorthite appears slightly rougher than that of orthoclase.

Cleavages, parallel to base (001) and brachy pinacoid (010), never intersect at right angles, as is the case in sections of orthoclase parallel to [_=b_] axis. This is due to the triclinic system of crystallization, but the divergence from a right angle is small (93° 36′ to 94° 10′).

[Illustration:

FIG. 72.—Plagioclase, showing crossed lamellæ, in olivine-gabbro. (From Cohen.)]

Inclusions at times may be quite important, as the vitreous inclusions of oligoclase in andesites, etc., and the iron ore inclusions and other microlites in labradorite. The arrangement of these inclusions may be zonal or in parallel orientation.

Double refraction is a little stronger than for orthoclase ($\gamma - \alpha$ = 0.008 to 0.013 (anorthite)), hence producing slightly brighter interference colors in sections of the same thickness.

Extinction takes place in all sections unsymmetrically with respect to crystallographic, twinning or cleavage lines (as these minerals are triclinic); hence extinction angles are always observed.

■Convergent Light■: All plagioclases show the emergence of a bisectrix,[107] more or less oblique, on brachy pinacoid (010) cleavage faces. These cleavage faces show no twin lamellæ, unless twinning after _Pericline_ law occurs, in which case the determination is much more complicated. The axial angle is large, 2_E_ = 155° (Albite). Optical character, depending on variety, (+) or (–).

■Alteration■: Partly the same as in orthoclase, forming clay, muscovite, etc. Calcite and epidote are more common as side-products, and zeolitization also occurs in some rocks. The plagioclases decompose more easily than orthoclase.

■Distinguished from■:

(_a_) ORTHOCLASE.—By repeated twinning after _Albite_ law, giving between crossed nicols a series of alternate dark and light bands.

When _Albite_ twinning is absent the distinction is very difficult.

(_b_) MICROCLINE.—By common absence of the microcline "_gridiron_" structure between crossed nicols.

Methods for Optical Determination of the Plagioclases.[108]

The correct determination of the particular plagioclase is of the greatest importance in the classification of rocks, and it is no longer sufficient to simply determine the feldspar as either orthoclase or plagioclase.

A quantitative analysis of isolated material would lead most surely to the desired result, but has many objections.

Modern optical methods now permit of a very accurate and convenient determination under ordinary circumstances. But of course these methods involve a knowledge of the approximate orientation of the section tested. When this section is not a definite cleavage fragment, its orientation can best be determined by convergent light tests.

Only an outline of these methods can be here given, and reference should be made to more complete works for an elaborate discussion of the subject.

It is very convenient to have at hand a set of glass models of the plagioclases, showing location of plane of optic axes, vibration directions and crystal axes.[109]

(1) _Schuster's_ method of recognizing the different feldspars by extinction angles measured on the cleavage plates[110] is very precise, but not always applicable for crystals in rock sections.

EXTINCTION ANGLES:

EXTINCTION ANGLES: ON BASE, MEASURED FROM TRACE OF ON BRACHY PINACOID, MEASURED FROM PINACOIDAL CLEAVAGE. TRACE OF BASAL CLEAVAGE. Albite + 4° Albite +19½° Oligoclase, Ab_{4}An_{1} + 2° Oligoclase, Ab_{4}An_{1} + 8° Labradorite, Ab_{1}An_{1} – 5½° Labradorite, Ab_{1}An_{1} –20° Anorthite –36½° Anorthite –41½°

Confusion may here arise between albite and labradorite if disregard be had to signs, but the more acid oligoclase is readily distinguished from the basic anorthite.

By convention the angles on base and pinacoids are (+) when the direction of extinction has apparently moved as the hands of a watch, with reference to the upper right hand edge (between base and pinacoid) of the crystal. When the reverse is true the angles are (–), see Fig. 73.

(2) The statistical method of _Michel Lévy_ and others is often applicable, especially in the following case:

Sections at right angles to the brachy pinacoid (010) and hence showing _Albite_ twinning.—These sections, as nearly perpendicular to the lamellæ as possible, are known by the sharp dividing lines, by the extinction angles on each side of the trace of the twinning plane being approximately equal and by the fact that the two adjacent lamellæ are of the same color when the trace of the twinning plane is parallel to the plane of vibration of either nicol. Also in the 45° position the lamellæ are exactly the same color and the dividing lines disappear. Measure the extinction angles in as many sections thus selected as possible and take the maximum value.[111] This should be very close to the maximum extinction angle, which is a constant for each kind of feldspar.

[Illustration:

FIG. 73.—Showing conventional signs of extinction angles.]

MAXIMUM EXTINCTION ANGLES IN SECTIONS PERPENDICULAR TO ALBITE TWINS. Albite 16° Oligoclase, Ab_{4}An_{1} 5° Labradorite, Ab_{1}An_{1} 27° Anorthite 53°

In the determination of rod-like microlites,[112] oligoclase extinguishes almost parallel to its length, while anorthite may show extinction angles of over 27°. When these microlites show _Albite_ twinning use the method just described.

(3) _Fouqué's_ method[113] can be used when the optical orientation of the section is known (as the result of a test with convergent light). The extinction angles of these known sections are of great diagnostic importance.

The best sections are those at right angles to the two bisectrices, and these may be obtained by rapidly testing those sections, in the rock, which show an interference color about half as high as the maximum color in the rock section, in this way avoiding the sections parallel to the optic axes.

Having found such a section, test it with a gypsum or ¼ undulation mica plate to prove whether the bisectrix is ■ a or c. If ■ a (these sections show sharp twinning striations) measure extinction angle between trace of axial plane and _albite_ twinning; if ■ c measure extinction angle between trace of axial plane and basal cleavage cracks.

EXTINCTION ANGLES IN SECTIONS:[114] ■ a, MEASURED FROM ALBITE STRIATIONS. ■ c, MEASURED FROM CLEAVAGE CRACKS. Albite 74° 19½° Oligoclase, Ab_{4}An_{1} 88° 5° Labradorite, Ab_{1}An_{1} 60° 22° Anorthite 55½° 48°

When both extinction angles can be obtained, the determination of the plagioclase is very certain, but the result cannot be regarded as definite when only one is found; and the method becomes more difficult as the crystals become smaller.

The position of the axial plane should be determined by convergent light test and not simply by the direction of extinction in parallel polarized light.

(4) _Michel Lévy's_ method[115] can be employed when twinning is present after both _Carlsbad_ and _Albite_ laws.

[Illustration:

FIG. 74.—Extinction Angles in the Zone normal to (010) in Carlsbad Twins of the Plagioclases.]

The section to be tested should be in the zone perpendicular to (010). Such sections show sharp boundary lines between the twin lamellæ and, between crossed nicols, the _Albite_ lamellæ show the same interference color when the trace of (010) is parallel to the cross-wires of the ocular, and also in the 45° position the lamellæ are the same color and no dividing lines show. The two parts of the _Carlsbad_ twin exhibit different interference colors in the 45° position, this difference being more marked as the composition approaches that of Anorthite. The extinction angles are measured from the trace of the _Albite_ twinning plane (010), paying regard to the + and – signs, and the _concurrent series_ of angles are to be obtained from the two parts of the _Carlsbad_ twin. The range of these angles (for four type compositions, Ab, Ab_{4}An_{1}, Ab_{1}An_{1} and An) is given in the accompanying diagram for all positions of the section in the zone normal to (010).

In the curves of this diagram (Fig. 74) the vertical distances are the extinction angles for every ten degrees measured from the trace of the _Albite_ twinning plane, and the horizontal distances represent varying positions of the section in the zone normal to (010) for every ten degrees of rotation from the position ■ to the edge (100)(010) (that is ■ _■_ axis), through a revolution of 180° to again ■ to the same position. The concurrent angles in one part of a _Carlsbad_ twin are represented by a heavy line and in the other part by a broken line. It will be observed that the difference between these concurrent angles is very small in Albite (3°) and increases markedly towards Anorthite (60°).

TABLE FOR BECKE METHOD.[116] Orthoclase ■ α ■< ω Quartz Microcline ■ β ■ „ Albite ■ γ ■ „
■■■

intermediate and basic composition.

Albite is found in granite (commonly intergrown with orthoclase), gneiss, etc., and frequently as a secondary constituent (secondary feldspar[119]) in the feldspar-quartz mosaic of mechanically metamorphosed rocks. It may also be present in acid eruptive rocks.

Oligoclase is very frequent in granite, syenite, gneiss, diorite, trachyte, andesite, diabase, etc.; and particularly accompanies orthoclase.

Labradorite is confined more to the gabbros,[120] basic eruptive rocks and crystalline schists, rich in amphibole and pyroxene.

Anorthite occurs in gabbros, the most basic porphyrites, basalts, etc.

Chemical corrosion and mechanical deformation[121] may take place as in orthoclase.

Anorthite and labradorite are more or less decomposed by hydrochloric acid, while albite and oligoclase are not acted on by the acid.

Especially interesting is the alteration of the plagioclase that takes place in gabbros, accompanied by “uralitization” of the pyroxene, forming “_saussurite_.” This consists of a white to greenish confused aggregate, chiefly of zoisite, grossularite, vesuvianite, chlorite, secondary feldspar (albite), etc.

Anorthoclase (a Na K, triclinic, feldspar).—Shows between crossed nicols intersecting areas of exceedingly fine composite twin structure and others of homogeneous structure, producing a watery or “moiré” appearance. The twin structure may be only seen in very thin sections. All possible kinds of perthitic intergrowth occur. Further distinguished from orthoclase by small extinction angle (4°) on base and by smaller axial angle (2_E_ = 72° to 88°).

Replaces orthoclase in the Na rich eruptives. Found in augite-syenite and “Rhombenporphyr” of Norway (with rhombic cross-section), acid augite-andesite of Pantelleria and in the porphyries of the Hartz.

CYANITE, Disthene.

ANISOTROPIC. BIAXIAL. TRICLINIC. COMPOSITION: Al_{2}SiO_{5}. ELONGATION ■ c′.

[Illustration:

FIG. 75.—Cyanite, macro pinacoid cleavage section.]

■Usual Appearance in Sections■: Blade-like crystals without terminal planes, but with cross-section (six-sided) showing two long parallel edges and four shorter edges; also in columnar aggregates. Twinning common, with generally twinning plane parallel to macro pinacoid (100). Colorless or bluish and spotted. The index of refraction is high (_n′_ = 1.720, α = 1.712, γ = 1.728), hence _relief_ marked and surface rough. Cleavage perfect, parallel to macro pinacoid (100), appearing as sharp cracks, parallel to longest edges in cross-sections; less distinct, parallel to brachy pinacoid (010). Fibrous parting parallel to base (001), Fig. 75. Pleochroism (colorless to blue ■ c′) not noticed except in colored crystals.

■Crossed Nicols■: Double refraction quite strong ($\gamma - \alpha$ = 0.016). Interference colors upper first order, yellow, red, violet, etc. _Extinction_ angles observed in all sections (being triclinic), reaching a maximum of 30° on macro pinacoid (100), Fig. 75. Extinction on base, about parallel to most perfect cleavage. In _convergent light_ axial angle large; axial plane and Bx_{_a_}. about perpendicular to best cleavage (100); optical character (–).

■Alteration■: Seldom observed, but may take place to mica.

■Distinguished from■:

(_a_) AMPHIBOLE by cleavage (intersecting cleavages at 124° in amphibole and 90° in cyanite) and by (100) cleavage plates of cyanite showing emergence of acute bisectrix.

(_b_) CORUNDUM by being biaxial.

Distinction from similar appearing minerals may be difficult.

REMARKS: Found in gneiss, granulite, metamorphic schists, ecolgite, etc., commonly associated with garnet. It is not attacked by acids. H., 5 to 7. Sp. gr., 3.6.

SERPENTINE.

AGGREGATE. ELONGATION (of fibers) ■ c′.

COMPOSITION: $H_{4}Mg_{3}Si_{2}O_{9}$, with replacement by Fe.

■Usual Appearance in Sections■: Dense, fibrous (chrysotile) or scaly (antigorite) aggregates.

Color.—Colorless to light greenish, except the Fe rich variety which is green.

Index of Refraction.—_n′_ = 1.55 to 1.56 (α = 1.56, γ = 1.571 for antigorite), hence no _relief_ and surface smooth.

■Polarized Light■:

Pleochroism.—Not seen or very feeble, except in the Fe rich variety.

■Crossed Nicols■:

Double Refraction.—Rather weak ($\gamma - \alpha$ = 0.009 to 0.011).

Interference Colors.—Middle first order, gray, white, yellow, etc. Anomalous colors do not appear. The aggregate structure is distinctly seen between crossed nicols. Due to compensation aggregates may appear isotropic.

■Distinguished from■: CHLORITE.—By more usual absence of color, pleochroism and anomalous interference colors; but this distinction may be very difficult.

REMARKS: Serpentine (both antigorite and chrysotile) is essentially a secondary mineral, resulting in most cases from the alteration of chrysolite (olivine), Fig. 22, more rarely of pyroxene or amphibole.[122] The alteration of olivine to antigorite leads to the characteristic “lattice structure,” the alteration to chrysotile to “mesh structure.” In the case of the “mesh” formation the alteration starts from the surface and cracks, producing fibres of chrysotile, which stand at right angles to these edges and cracks. As serpentinization proceeds new cracks form, due to increase in volume, and the process may continue until complete pseudomorphism takes place. When this subsequent serpentinization of the meshes takes place the resulting serpentine may appear almost isotropic[123] and is certainly different from the chrysotile of the first formed veins (Weinschenk). Pieces of the parent mineral are often present.

Serpentine is found in ophiolites, the altered basic igneous rocks, pyroxenites, peridotites, etc., and as a primary mineral in the Central Alps peridotite, intergrown with fresh olivine (Weinschenk). It may also form a rock by itself. Serpentine is attacked quite strongly by hydrochloric acid, still more so by sulphuric acid. Common serpentine is not altered by heating (distinction from chlorite), but the Fe rich variety becomes brown and opaque. H., 2.5 to 4. Sp. gr., 2.5 to 2.7.

CLAY, Kaolin.

COMPOSITION: AGGREGATE. $H_{4}Al_{2}Si_{2}O_{9}$ (kaolinite).

■Usual Appearance in Sections■: Fine, scaly, colorless aggregates, which appear opaque (due to porous structure). The scales show basal cleavage. Index of refraction is about the same as balsam (_n′_ = 1.55), hence no _relief_. The double refraction is weak ($\gamma - \alpha$ = 0.008).

■Distinguished from■: Colorless MICA and HYDRARGILLITE [$(Al(OH)_{3})$, which as an alteration product of the feldspars is often confused with clay] by weak double refraction.

REMARKS: Clay results from the alteration of the feldspars (especially the plagioclases), elæolite, scapolite and other silicates. Kaolinite is insoluble in hydrochloric but decomposed by sulphuric acid. H., 2.5. Sp. gr., 2.6.

CHAPTER V. METHODS OF PREPARING SECTIONS.[124]

The methods described will be those used in making rock sections. The general principles involved are the same for both rock and crystal sections; although more difficulties are encountered in making the latter, due to the sections being required in some definite direction or of some precise thickness, or on account of the possibly fragile or brittle character of the crystals.

In the case of rock sections any section, taken “at will” through the rock, will generally do.

Cutting and Grinding Machines.[125]

Many different kinds are used, the power being furnished by steam, electric motor[126] or by the hand or foot.

The chip or fragment of rock to be sliced should be comparatively small in size, and may be cut by either a vertical diamond saw or by a horizontal emery-disc. The fragment is held in position by suitable guides. The moistened emery can be kept in the tray and fed to the disc by a spoon or some other device. Diamond saws are only needed in the case of hard rocks.

For cutting sections of crystals in definite directions a form of small hand apparatus[127] is shown in Fig. 76.

This cut shows how the plate, to which the crystal is cemented, can be given definite rotation in two directions. The simpler crystal holder, appearing loose on the stand, may be used when a section is required parallel to the face of the crystal cemented to the holder.

In these machines the cutting is done with rotating saws of sheet-tin, usually charged with either diamond dust or emery.

[Illustration:

FIG. 76.]

In the case of a very small crystal a section, parallel to any desired face, can be obtained by cementing this face to a suitable frame or holder and grinding down by hand on a glass plate with emery, the final polish being given with rouge. When the section required is not parallel to a crystallographic face or cleavage it must be verified geometrically with reference to other faces. If the crystals are soluble in water, some other liquid, as α bromnaphthalin or benzine, must be used in grinding; and very fragile crystals are rubbed down on a ground glass plate without emery or rouge, simply using bromnaphthalin or some other appropriate liquid.

When sections of a crystal are desired with strictly parallel faces, the form of grinding apparatus shown in Fig. 77 can be used.

This apparatus consists of a cylinder, held within a suitable frame supported on three set-screws, _a_{1}_, _a_{2}_ and _a_{3}_, of hard steel. The lower surface of the frame and consequently the bottom of the cylinder can be adjusted by the wedge _k_ and the set-screws so that it is exactly parallel to the grinding surface of the glass plate. The crystal to be ground down, _p_, is cemented to the bottom of the cylinder, and the whole apparatus rubbed over the grinding surface of the plate. The pressure of the hand on the upper part of the cylinder regulates the pressure of the crystal on the grinding surface. In this way a surface is obtained which is exactly parallel to the surface cemented to the cylinder.

[Illustration:

FIG. 77.]

Sections of definite thickness can also be obtained by using this apparatus; for the adjustments with the wedge _k_ may be so arranged that, when the stop _t_ in the cylinder has reached the bottom of the slot in the frame, the lower surface of the cylinder will be the required distance from the grinding surface of the glass plate. The wedge is graduated so that the value of one division on the sloping top is known in _mm._ of vertical distance.

Saws.

Saws,[128] of about six inches in diameter made from ½■■ inch sheet-tin, are convenient for general work, and may be charged with diamond dust by the operator as follows:[129] Crush one or two carats of rough crystals of diamond-bort in a small steel mortar to about the condition of fine sand, care being taken not to reduce the diamond to powder. Transfer the dust to a piece of flat iron and, after collecting it in a heap, moisten with a drop of oil. The cutting edge of the tin disk must now be prepared by making a series of incisions (½■■ inch deep) on the outer margin. This can be done by striking the disk with a sharp, thin knife edge. The larger the number of incisions and the closer they are together the better. Charging the saw is accomplished by gently hammering the edge against the iron plate, upon which is the paste of diamond dust and oil. The disk must be slowly rotated during this

charging process, which should be continued until all portions of the edge have been gone over two or three times.

Instead of charging with diamond dust the saws may be used with emery. The edges of the saws should first be “upset,” as just described, and then while rotating charged with emery. The emery in the state of mud can be applied with the thumb and fingers, or the saw can be allowed to pass through a tray of emery mud. The finer grades of emery (Nos. 100 to 120) should be used.

The method of mounting saws, of course, depends on the way the saws and spindles are constructed. It is well, however, to have the hole in the center of the saw-disk sufficiently large to allow of adjustment for accurate centering.

Cutting.

During the process of cutting a lubricant must be used on the saw. Petroleum has been recommended by some, but water seems to be the most used. Holding a piece of soap against the cutting edge will also reduce friction. It is convenient to carry the water to the saw through a very small lead pipe, which permits of easy adjustment, so that the water can be delivered at just the right spot, the flow of water, of course, being regulated by a stop-cock.

Another method for cutting sections is used by the U. S. Geological Survey at Washington, D. C. The apparatus consists of an endless wire of soft iron, about ⅜■■ inch in diameter, revolving over two pulleys or wheels, one of which is driven by steam-power. The wire is charged by dipping the fingers in water, taking up a little fine (120 grade) emery and holding the fingers against the wire above the section. The wire revolves so as to cut downwards, thus carrying with it the emery taken from the fingers.

In cutting sections the thickness, of course, depends on the character of the rock; the more porous and fragile the rock the thicker the section should be made, an ordinary section being about as thick as a silver quarter of a dollar.

Very often by skill and practice a suitably shaped chip or fragment can be detached from the specimen with a hammer or with a hammer and cleavage chisels, thus avoiding the delay and trouble involved in the use of the section cutter.

Grinding Plates or Laps.

Copper laps, about 7–8 inches in diameter and ½ inch thick, seem to be best for general purposes; although laps made of lead or cast iron are also used. A lead lap, being soft, holds the emery well and thus hastens the grinding away of the section; but at the same time its own smooth surface is soon destroyed. A cast iron lap is much harder and retains its smooth surface better, but does not hold the emery so well and therefore retards the process of grinding. Copper, being intermediate in hardness between lead and iron, seems to combine the advantages of both.

It is always good practice to have at least two laps, one for the preliminary grinding with coarse emery and the other for the final grinding with the finest grades of emery. In this way one lap is always kept with a smooth surface, making it possible to give a uniform, plane finish to the section.

The surface of the laps should not be exactly plane, but turned or finished so as to be a little higher (⅛■■ of an inch for diameter of 8 inches) at the axis than at the periphery; the idea being to compensate for the more rapid abrasive action towards the periphery.

Cementing.

For grinding down to a proper thinness for transparency it is necessary to _cement_ the fragment of rock to a holder, which consists of a small piece of plate-glass about ■ inch thick. If the piece of rock has been cut by a good diamond saw the surface will be comparatively smooth and uniform, and may only need polishing (described under _grinding_) before cementing. When, however, the piece of rock is in the shape of a chip or rough fragment it is first necessary to prepare a smooth ground surface on one side (described under _grinding_) before it can be cemented to the glass holder.

The pieces of plate-glass used should be free from flaws, bubbles or anything tending to destroy uniformity of surface, and should be a little larger than the chips and slices of rock for which they are to act as holders. Hardened Canada balsam, or better yet, a cement made of a mixture of shellac and Venice turpentine,[130] should be used.

The process of cementing is carried on as follows: Heat the glass support over an alcohol lamp or a Bunsen burner, place it on a good non-conductor of heat, as a piece of wood, and rub it with a stick of the cement until a sufficient quantity has been melted off. The piece of rock should then be treated in the same manner, applying the cement to the smooth finished portion. Care must be

taken that neither the glass nor rock preparation are heated too much, as this would cause the cement to smoke or bubble. After placing the rock preparation and plate together, use quite a little pressure in order to drive out all superfluous cement. Examine now, through the glass, the contact surface and see that it is entirely free from bubbles, etc.

Bubbles are usually caused by overheating of the parts before cementing. If only very few bubbles are seen, they may generally be removed by moving the rock preparation rapidly back and forth over the glass plate. If the bubbles are numerous or cannot be removed in the manner just described, the rock preparation must be separated from the glass plate and the cementing done over again.

Bubbles must _not_ be allowed to remain, as the portions of the rock over them, not having any cement backing, are ground away leaving holes in the section.

Grinding.

After the rock preparation has been cemented to its glass holder it is ready for the grinding process, for which are used horizontal laps, mounted on a vertical spindle in the tray _T_, Fig. 76. The copper lap for the first grinding is put in place, and, after it has commenced to rotate, is charged with emery and water. This can conveniently be done by dropping on the emery and water, either with the fingers or with a small bunch of rags at the end of a stick. A large camel's hair brush may be used for putting on the finest emery. The emery is distributed over the rotating lap by the motion of the rock preparation during grinding. The kind of emery used for this first grinding depends somewhat on the character of the rock section. If the section is composed of a hard, compact, fine grained rock, the first emery used may be quite coarse; the coarser the emery the more rapid being the grinding down. For rough, quick work, Nos. 80 to 100 emery can be used until the section becomes quite thin; then, still using the same lap, substitute the finest corn emery (next coarsest to flour emery) and continue grinding until the section becomes quite translucent. The lap must then be changed, and the grinding finished with the finest emery dust.

Too great care cannot be given to cleanliness while doing this sort of work. A single grain of coarse emery, getting on the lap or section during the final grinding, will often spoil the whole work by making a bad scratch. In grinding down the section, great care must be taken to see that the grinding surface is kept parallel to the surface cemented to the glass. The section is firmly pressed against the lap by means of two or three fingers, depending on its size, and uniform pressure should be maintained over all parts.

The section should be examined frequently, and if it is noticed that one part is thicker than another, place the section on the lap so that the thicker part is towards the periphery, and put a little more pressure upon this part. Gutting or grooving the copper laps is prevented by moving the section from center to periphery and back, at the same time giving to it a slight rotary motion. It is best to have the lap revolve from right to left (in the opposite way from the hands of a watch), as, holding the section on the right side of the lap, it is easier to keep it in place by a pulling motion rather than by pushing it against the motion of the lap. In the final stages of grinding and polishing great precaution must be exercised, as one or two turns too many of the lap will often tear away a large part of the very thin section. The section should be frequently examined, by transmitted light, with a small, low power microscope, a drop of water or oil being put on the section to render it more transparent. If the section is thick and fastened to the plate-glass with a good deal of cement, it will be found convenient, after the section has been ground quite thin, to remove most of this cement from around its edges. If this is not done, it may delay the final work of grinding down. A good rock section should be made so thin that all the transparent and translucent component minerals can be examined and studied. Well made rock sections average in thickness from 0.03 to 0.05 _mm._ The last part of the final grinding and polishing can be done by the hand on a ground glass plate, using the finest emery dust or rouge and water.

Flour emery may also be used entirely for grinding, and the finest emery dust for polishing. The finer emery makes better work, although it takes more time, and is much safer for porous or brittle sections, as the danger of tearing away pieces of the section is avoided. In the case of a porous or decomposed rock it is well before grinding to boil the section in Canada balsam or other equivalent material so as to fill all the pores and interstices, thus making the section more compact and less liable to chip away. Sometimes it may even be best before grinding to mount the section on its permanent glass slide, so that when it has been ground thin enough the cover can be put on without running any risk in transferring the section. The only objection is that the glass slide may be a little scratched by the emery.

Mounting.

When the section is sufficiently thin and has a smooth uniform surface it is ready to be transferred and mounted upon its permanent glass slide. The glass plate, which has held the section during the grinding, is gently heated, and, as soon as the cement begins to soften, the section is very gently pushed off into a shallow cup or evaporating dish containing turpentine or alcohol. Turpentine is convenient for general use, because common alcohol (on account of the water it contains) unites with the shellac to form a kind of white pasty substance, which is sometimes hard to remove from the section. The section should be carefully cleaned in the turpentine or alcohol bath by means of fine camel's hair brushes. A section-lifter, made from a piece of broad, flat watch-spring fastened to a small handle, is then gently placed under the section, which is lifted out of the bath in an inclined position so as to allow the liquid to drain off. If a drop still adheres it can be removed by touching it gently with the finger.

The section is now placed in a tray, upon a piece of white, unglazed paper, so that it may thoroughly dry; after which process it is transferred to a glass slide, and, if necessary, its rough edges chipped off with a knife.

If the section is very large, and it is desired to mount it in two pieces, it can easily be divided by holding one half tightly between two glass slides and gently bending the other half with the fingers. The fracture will take place along the edges of the glass slides.

A mixture of gum damar and benzole is recommended for mounting, the claim being made that gum damar does not turn yellow with age, whereas Canada balsam may do so. Two solutions of gum damar and benzole are used. One very thin, about the consistency of water, the other quite thick, about the consistency of mucilage. Both solutions are prepared by dissolving the gum damar in benzole and filtering through a linen or silk rag. If the solution is too thin it can be thickened by placing the bottle in a warm place and allowing the excess of benzole to evaporate, or if too thick, more benzole can be added. It is convenient to keep the solutions in short glass bottles, with wide necks and glass covers instead of corks. The solutions can be applied with glass rods.

When the section is all ready for its final mounting it is carefully centered with a coarse needle on the glass slide,[131] and a drop of the thin solution placed at the edge of the section. Capillary attraction will cause it to flow over the glass slide under the section, and while it is soft the section can be again adjusted in place. The slide is then placed in a cool, dust proof place and allowed to stand for about twelve hours, when the cement will be set and the section held firmly in place. The upper surface of the section is then washed with a drop of benzine, and as much as may be necessary of the thick mounting solution placed upon it with a glass rod. A cover of glass of the right size is gently heated and placed in position over the section. Care must be taken not to have the cover too hot, as it would cause bubbles to form in the cement. It is also best to rest one edge of the cover on the cement first, and then lower it gently so as to prevent air bubbles from being included. The cover is adjusted and then held firmly in position by means of a mounting clamp, which presses out all superfluous cement. If a few small bubbles remain near the edges they may be let alone, as they will generally work out by themselves in time. Sometimes a large bubble can be worked out by local pressure with the finger and gentle heating with a small iron rod. If the mounting is unsatisfactory the cover should be removed by heating, the old cement washed off with a camel's hair brush and benzole, and a fresh cover put on. After the cement has set, the clamp may be removed, but the slide should be left for 24 hours, or longer if necessary, until the cement is quite hard. This takes longer in hot than in cold weather.

The advantage of using two solutions for mounting is that the section is firmly held in place on the glass slide while the cover is being placed over it; there is thus no slipping or sliding of the section, and when the cover is adjusted in place the work is well finished and the section still in the centre of the slide.

Canada balsam, or balsam in xylol, are also often used for mounting. The advantage of the latter being its quick drying or "setting."

Cleaning and Finishing.

When the cement has set the superfluous part is singed by means of a small hot iron rod. Care must be taken not to use too large a rod or to have it too hot, as the cement under the cover might then soften and allow the cover to slip or air bubbles to form. The singeing drives off the more volatile part of the cement, leaving only a brittle residue, which can be easily scraped off with a knife. In some cases it may be necessary to singe and scrape twice. The final cleaning is done with a soft rag and benzole. The slides are now ready to be marked, either with a diamond pencil or with pasted labels.

Convenient Apparatus for Work in a Petrographical Laboratory:

Section lifters made of watch springs, three sizes.

Section holders or clamps for pressing out superfluous cement.

Needle points mounted in light handles.

Easy spring forceps.

Mounting frame for centering section on glass slide.

Small iron rod for singeing.

Small camel's hair brushes.

Cutting pliers and forceps.

Set of wooden section trays.

Glass stopper bottles for benzole, benzine, turpentine and alcohol.

Open neck bottles, with covers for two mounting liquids.

Rotating mounting stand.

Small microscope for testing transparency of section.

Glass rods.

Small squares and rectangles of plate-glass.

Round, oval and square cover-glasses.

Glass slides with ground edges.

CHAPTER VI. CHEMICAL AND MECHANICAL TESTS.

These tests may be necessary to confirm an optical determination or to assist in the differentiation of the closely related species of a group, as for example, the different plagioclases in the feldspar group. They may also be useful in the case of opaque substances.

The ordinary chemical methods employed in mineral analyses are often not applicable, on account of the minute size of the mineral under investigation and the lack of sharpness in the reactions. Those methods[132] are to be preferred which produce crystallizations independent of the relative proportions of the materials taking part in the reaction and also of the physical conditions invoked.

The tests can be made either on the crystal in a rock section or on the isolated crystal or fragment, the latter method being preferable when possible.

CHEMICAL TESTS MADE ON CRYSTAL IN SECTION.

The part of the section to be tested must be prepared by thorough washing with alcohol and benzole to remove all traces of balsam. If the section is covered, the cover-glass can be cut across with a diamond, and, after heating, the desired portion removed with a knife edge. Any portion of a section can be isolated by surrounding it with a rim of viscous balsam or by putting on a new cover-glass, in which a small hole has been made.[133] This hole can be accurately adjusted over the special portion of the section and the balsam removed by alcohol and benzole.

The treatment of rock sections with ordinary acids, such as hydrochloric, may show the presence of easily soluble minerals[134] and carbonates, or distinguish silicates that are soluble with jelly, or produce etched figures on the minerals.

Test for Carbonates. When only present in very minute grains the test can be made as follows: Cover the rock section with a drop of water and a cover-glass, then allow a drop of acid to slowly diffuse through the water film. The glass cover will prevent the escape of the gas bubbles[135] which will thus surely be detected.

If necessary the section can be warmed by heating the projecting part of a suitable stand, placed under the section on the stage of the microscope.

Test for Gelatinizing Silica. Cover the carefully cleansed section with a little dilute acid (commonly hydrochloric) and let stand. If too much acid is used the resultant gelatin will spread over the whole section and not appear simply on the gelatinizing silicate. Warm the section, if necessary, and finally rinse off the remaining acid thoroughly with water. Do not allow the action of the acid to continue too long, as it is desirable to obtain only a very thin film of gelatinous silica over the minerals attacked, so that the optical tests can still be made on these minerals. If after the first trial the action has not been pronounced enough, the test should be repeated.

The transparent film of gelatinous silica is made more visible by covering the section with a drop of water, containing a dilute solution of fuchsine. After standing for some time the section should be washed, when only those portions covered by the gelatinous film will show the color stain.

ETCHED FIGURES.[136]

The results of etching tests can not be regarded as very satisfactory in the case of sections of minerals in rock sections, on account of doubt as to the crystallographic orientation of these sections.

The symmetry of the etched figures depends essentially on the relation of the crystal faces on which they are obtained to the planes of symmetry.

The forms of the etched figures differ on the same face of a mineral, depending on the reagent used, but their degree of symmetry is independent of the reagent or its degree of concentration. The sharpest figures are produced on crystal and cleavage faces, the figures being less perfect on artificially prepared faces, even when polished. The etching tests may, however, be tried to prove the presence of twinning, or to distinguish between minerals of similar appearance but belonging to different systems.[137]

Various acids or alkalies are used to produce the etched figures, depending on the mineral to be tested. Different factors influence the formation of good etched figures, and that method must be used which seems to give most satisfactory results in the given case. The action of the reagent should be sufficiently pronounced to develop clearly the etched figures; at the same time the tests must be stopped before the solvent action has been too powerful.[138] After treatment for etching the section should be thoroughly washed and examined in some fluid of weak refraction (with _n_ lower than that of the crystal section), such as water or air.[139] The objective, of course, must be focused on the surface of the section.

HEATING SECTIONS TO REDNESS.[140]

The part of the section to be tested must be removed from the object glass, carefully cleansed of balsam, and held on platinum foil in the oxidizing blowpipe flame. After the test the fragment used may be remounted in Canada balsam for study.

As a result of heating:

Colorless, hydrous minerals (zeolites and chlorites) become cloudy in appearance.

Colorless silicates, containing protoxide of iron (as olivine, or faintly colored pyroxene or amphibole), become red or reddish-brown.

Colored minerals may change their color, chloritic substances becoming brown or black if heated enough.

Hornblende always becomes pleochroic, and olivine sometimes becomes so.

Members of the sodalite group may be turned blue, if not already of that color.

The dichroism (yellow to blue) of almost colorless iolite may be developed.

Carbonaceous particles may be distinguished from the iron oxides by being consumed.[141]

METHODS OF ISOLATING CRYSTALS OR MINERAL FRAGMENTS FOR TESTING.[142]

For the application of these methods the rock or aggregate of minerals should be reduced to homogeneous[143] grains of uniform size (preferably crystals or cleavages) and not to powder. This is best done by pounding in a metal mortar, avoiding all grinding motion.

The separations required may be made by specific gravity solutions or magnetic methods, alone or combined; and in some cases may be assisted by chemical action.

When other methods fail it may be necessary to separate single grains from a mixture by hand. A grooved piece of plate-glass, passed beneath the objective of the microscope, will be found useful. The desired grains in this groove can be picked out by means of a piece of fine waxed thread or a fine pointed stick moistened at the end.

The _hardness_ of the homogeneous grains may be obtained by pressing them firmly into the end of a lead stamp or holder and trying the effect of scratching upon the faces of minerals of known hardness.

Specific Gravity Separation.[144] Accomplished by use of fluids of different specific gravity. These fluids can be made specifically lighter by dilution, and hence the fragments will fall to the bottom in order of decreasing density. Dilution of the heavy solutions to any specific gravity may be affected empirically until the solution will just suspend a fragment of a mineral having the desired specific gravity; or the exact specific gravity of the solution may be determined by the Westphal balance.

The following _indicators_ may be employed to determine the limits of the specific gravity of the solution to be used for separation purposes (V. Goldschmidt):

NO. NAME. LOCALITY. SP. GR. 1. Sulphur, Girgenti, 2.070 2. Hyalite, Waltsch, 2.160 3. Opal, Scheiba, 2.212 4. Natrolite, Brevig, 2.246 5. Pitchstone, Meissen, 2.284 6. Obsidian, Lipari, 2.362 7. Pearlite, Hungary, 2.397 8. Leucite, Vesuvius, 2.465 9. Adularia, St. Gotthard, 2.570 10. Elæolite, Brevig, 2.617 11. Quartz, Middleville, 2.650 12. Labradorite, Labrador, 2.689 13. Calcite, Rabenstein, 2.715 14. Dolomite, Muhrwinkel, 2.733 15. Dolomite, Rauris, 2.868 16. Prehnite, Kilpatrick, 2.916 17. Aragonite, Bilin, 2.933 18. Actinolite, Zillerthal, 3.020 19. Andalusite, Bodenmais, 3.125 20. Apatite, Ehrenfriedersdorf, 3.180

Among the heavy solutions employed may be mentioned:

Thoulet's solution of potassium-mercuric iodide (KI: HgI_{2} = 1: 1.24), maximum specific gravity 3.196. Klein's solution of cadmium borotungstate ($2H_{2}O$, 2CdO, $B_{2}O_{3}$, $9WoO_{3}$ + $16H_{2}O$), maximum specific gravity 3.6. These two solutions can be mixed with water in any proportion without being decomposed. Solution of barium mercuric iodide, maximum specific gravity, 3.588, cannot be diluted with water. Methylene iodide ($CH_{2}I_{2}$), specific gravity 3.3243 at 16° C. varying with the temperature, can be diluted with benzole but not with water.

Nitrates of silver and thallium[145] ($AgNO_{3}$: $TlNO_{3}$ = 1.1) fuse at about 75° C. to a clear mobile liquid with specific gravity over 4.5. Can be mixed while melted with water in all proportions; but cannot be used for separation of sulphides, as these nitrates are attacked by them.

Possible chemical action between the minerals and heavy solutions must not be overlooked in this method of separation.

The funnel-shaped apparatus for these separations must be so arranged, with stop-cocks, etc., that the heavier material collected at the bottom can be easily drawn off or removed at any stage of dilution.

These separations, for various reasons, are not always complete, but the best results are obtained when the processes are repeated several times.

Electro-magnetic Separation. All iron-bearing minerals may be separated from those free from iron by an electro-magnet.

The factors influencing the attraction of a mineral by an electro-magnet are not definitely known, and do not seem to depend only on the percentage of iron.

Minerals, such as amphibole, pyroxene, epidote, olivine and garnet (containing iron), may often be separated by an electro-magnet by regulating its magnetic intensity.[146]

Separation by Chemical Means. Very many different methods may be used, depending on the nature of the work to be accomplished; but they are generally only reliable in the hands of a good chemist. The material should be in the state of fine powder.

As an example may be mentioned the treatment with pure concentrated HFl, by which the minerals of a rock are attacked in a certain sequence, the feldspars and related minerals first, then the quartz and finally the ferro-magnesium silicates, such as amphibole, pyroxene, olivine, etc.

MICRO-CHEMICAL REACTIONS.

The first requisite is to bring the substance to be investigated into solution. This can be done in the case of non-silicates by the ordinary solvents, while silicates can be decomposed and investigated either by the methods of Borichy or Behrens. Both methods rest upon the recognition of the forms, etc., of artificially produced crystals.

The size of a fragment for testing may vary, according to circumstances, from that of a poppy seed to a pin head. Good results are recorded from fragments of not more than 0.2–0.7 sq. mm.

The substance to be tested is placed on glass, protected by a film of balsam, and covered with a spherical drop of the solvent,[147] which should be allowed to act until all the different elements composing the sample are in solution (in the case of a very small fragment until it has all dissolved). Transfer the solution to another protected object glass, and, after evaporation, the crystallizations characteristic of the different elements will be seen.

If the evaporation is too rapid and the crystallizations incomplete, the residue should be redissolved in water, or a very dilute solution of the solvent employed, transferred to a fresh glass and allowed to recrystallize.

Borichy's Method.[148] (Hydrofluosilicic Acid.)

This method has the advantage of simplicity of manipulation and relative distinctness in results; but on the other hand these results are only obtained after several hours, and the temperature has an influence on the crystalline forms obtained. It is well to make the tests in a temperature of about 15° C.

Put a spherical drop of pure hydrofluosilicic acid[149] on the fragment and leave it for some hours in damp air until the action has been sufficient, then transfer it to a dry air bell-glass and allow evaporation and crystallization to take place.

For the microscopic examination the objective (200–300 diams. best for these observations) can be protected with glycerine and a mica disc or thin cover-glass, or the drop can be all evaporated and the crystals covered with liquid balsam and a cover-glass.

Crystallizations Obtained by Borichy's Method.

Potassium. From hydrofluosilicic solutions,[150] isotropic, colorless crystals of $K_{2}SiFl_{6}$, in cubes, octahedra or combinations of these forms with the rhombic dodecahedron. Apparently orthorhombic crystals may form from acid solutions and at a low temperature, but if these crystals are dissolved in hot water and recrystallized they will assume the normal forms.

Platinic chloride will produce under proper conditions sharp, yellow octahedra of $K_{2}PtCl_{6}$.

[Illustration:

FIG. 78.—Fluosilicate of potassium.[151]]

[Illustration:

FIG. 79.—Fluosilicate of sodium.[151]]

Sodium. From hydrofluosilicic solutions, colorless, very weakly doubly refracting, hexagonal crystals of $Na_{2}SiFl_{6}$, which are generally longer the higher the percentage of sodium in the solution. This test is very certain even for small amounts.

[Illustration:

FIG. 80.—Fluosilicate of calcium.[151]]

[Illustration:

FIG. 81.—Fluosilicate of magnesium.[151]]

Calcium. From hydrofluosilicic solutions, monoclinic crystals of $CaSiFl_{6} + 2H_{2}O$ of various forms, generally spindle-shaped, with not very strong double refraction. The crystals have seldom straight-edged boundaries and are often grouped in rosettes. The addition of dilute $H_{2}SO_{4}$ decomposes the crystals, recrystallization yielding long prismatic crystals of gypsum (distinction from strontium).

Treatment with HFl and dilute H_2SO_4 (in excess), producing on evaporation characteristic crystals of gypsum, furnishes a very delicate test for small percentages of calcium.

Magnesium. From hydrofluosilicic solutions, rhombohedral crystals of $MgSiFl_6 + 6H_2O$ with plane faces and sharp edges. The crystals are colorless and strongly doubly refracting with positive optical character, Fig. 81.

The formation of struvite crystals ($NH_4MgPO_4 + 6H_2O$), of coffin-like forms, is very characteristic and takes place from very dilute solutions (rendered alkaline) on the addition of a grain of salt of phosphorus or a drop of sodium phosphate.

Iron. From hydrofluosilicic solutions, crystals of $FeSiFl_6 + 6H_2O$, which are isomorphous with those of magnesium salts, with the same optical characters. They may be differentiated by moistening with potassium ferrocyanide or ammonium sulphide, in the first case by turning blue, in the second case black.

Aluminium. From hydrofluosilicic solutions, not satisfactory on account of the gelatinous formation.

When the gelatinous formation is obtained by the action of hydrofluoric acid on an _aluminous silicate_, the staining test can be used to distinguish between fine grains of feldspar and quartz or iolite and quartz.

Behrens' Method.[152] (Hydrofluoric and Sulphuric Acids.)

This method depends on common reactions that can be made rapidly, but has the disadvantage of being rather complicated and requiring delicate manipulation.

The tests are best made upon about ½ mg. of powder with HFl (pure and fuming). As soon as the fluorides begin to dry treat with dilute H_2SO_4 and warm until white fumes of SO_3 appear. In this way the HFl and $SiFl_4$ are driven off and the sulphates are left. This part of the test can conveniently be made on a piece of platinum foil. Add excess of water and concentrate.

Transfer a drop to a clean object glass and, while still liquid, examine it with the microscope. Do not use a cover-glass over the drop.

Crystallizations Obtained by Behrens' Method.

Potassium. Add a little platinic chloride when octahedral crystals of K_2PtCl_6 (size .18 to .30 mm.) will appear, which are clear, bright yellow in color with strong refraction.

[Illustration:

FIG. 82.—Potassium platinic chloride.[153]]

[Illustration:

FIG. 83.—Sulphate of calcium (gypsum).[153]]

Sodium. Use sulphate of cerium and allow a small amount of this reagent to act through a capillary pipette upon a drop of the solution. Very small aggregates of brown crystals (size .02 mm.) of the double sulphate of cerium and sodium are formed, which are clearly visible with 600 diams. If potassium is present the double sulphate of that alkali will appear in larger, grayish grains (size .05 to .06 mm.). An excess of H_2SO_4 is to be avoided.

Calcium. After a few minutes little gypsum crystals ($CaSO_4 + 2H_2O$) will appear. In strongly acid solutions the thin acicular crystals will be grouped in bushes or stars; in neutral solutions the crystals will have the normal shape of selenite crystals or form swallow-tailed twins.

Magnesium. Use salt of phosphorus dissolved in water and allow it to mix with the solution (to which has been added ammonium chloride and ammonia) through a capillary pipette. From a solution containing more than 5 per cent. of magnesium are first deposited X-shaped skeletons and rudimentary crystals of $Mg.NH_4.PO_4 + 6H_2O$. If the solution is more dilute beautiful, sharp, hemimorphic crystals (.10 to .20 mm. in size) of the orthorhombic system will appear. These crystals often resemble the roof of a house. The formation of the crystals is assisted by heat. Iron and manganese phosphates yield crystals of the same type, but the iron is separated on the addition of ammonia.

Aluminium. Use chloride of cæsium. Take a drop of the solution, with excess of H_2SO_4 driven off, and touch it with a platinum wire that has been dipped in the melted chloride of cæsium. Large crystals (.40-.90 mm. in size) of cæsium alum will form, which are octahedral and cubo-octahedral in shape. Iron does not interfere, as its crystallization would take place much more slowly. The solution should not be too concentrated.

[Illustration:

FIG. 84.—Magnesiumammonium phosphate.[154]]

[Illustration:

FIG. 85.—Cæsium alum.[154]]

Special Tests.

Distinction between haüynite (contains $CaSO_4$) and noselite (contains Na_2SO_4). Treat with HCl and on evaporation the characteristic crystals of gypsum will be seen if the mineral is haüynite. Dilute acid should be used and as low a temperature maintained as possible, otherwise crystals of anhydrite would form instead of gypsum.

Recognition of apatite by test for phosphorus. Treat with a drop of ammonium molybdate dissolved in HNO_3. After complete action remove the solution to a clean object glass, when after slight warming a large number of very small yellow crystals (rhombic dodecahedral in shape) will form. The test may be used to distinguish this mineral from nephelite, melilite and natrolite. In the presence of soluble silica evaporate to render it insoluble and treat again with HNO_3 and the reagent.

Other micro-chemical tests are not mentioned for the reason that in elaborate chemical investigations of sections or isolated fragments recourse should be made to the most complete publications on the subject.

APPENDIX.

BRIEF SCHEME OF CLASSIFICATION INTO SYSTEMS BY OPTICAL DETERMINATIONS.

■HOMOGENEOUS.■ The whole substance shows the same optical character, except in the case of twin crystals when the different portions of the twin are affected differently.

■Isotropic■ All sections of the substance remain dark during a complete rotation between crossed nicols, and no interference figure is produced by convergent light.

Amorphous Absence of crystalline form or cleavage.

Isometric Presence of crystalline form or cleavage.

■Anisotropic.■ Sections generally show some interference color and extinguish four times, at 90° apart, during complete rotation.

Uniaxial. Determined by character of interference figures obtained by convergent light from sections which remain dark or nearly so during complete rotation.

All sections show parallel or symmetrical extinction.

Tetragonal Sections giving interference figures are four- or eight-sided, or show rectangular cleavage.

Hexagonal Sections giving interference figures are three-, six- or nine-sided, or show cleavage lines intersecting at 60°.

Biaxial Determined by character of interference figures obtained by convergent light.

Orthorhombic Extinction is parallel or symmetrical in all sections parallel to _■_, [_=b_] and _■_. Color distribution is symmetrical to two lines and to the central point, see p. 48.

Monoclinic Extinction is only parallel or symmetrical in sections parallel to the ortho axis [_=b_]; all other sections show extinction angles. Color distribution is only symmetrical to one line or to the central point, see p. 48.

Triclinic Extinction angles in all sections, although in some minerals these angles may be very small. No symmetry in color distribution, see p. 48.

■AGGREGATE.■ Not homogeneous, but made up of an aggregation of individuals, all extinguishing at different times.

ORDER OF CONSOLIDATION OF THE CONSTITUENT MINERALS IN PLUTONIC ROCKS.

“There is in plutonic rocks a normal order of consolidation for the several constituents, which holds good with a high degree of generality. It is in the main, as pointed out by Rosenbusch, a law of ‘decreasing basicity.’ The order is briefly as follows:

“1. Minor accessories (apatite, zircon, sphene, garnet, etc.) and iron ores.

“2. Ferro-magnesian minerals—olivine, rhombic pyroxenes, augite, ægirine, hornblende, biotite, muscovite.

“3. Felspathic minerals—plagioclase felspars (in order from anorthite to albite), orthoclase (and anorthoclase).

“4. Quartz, and finally microcline.

“In most rocks such minerals as are present follow the above order. The most important exceptions are the intergrowth of orthoclase and quartz and the crystallization of quartz in advance of orthoclase in some acid rocks, and the rather variable relations between groups 2 and 3 in some more basic rocks. The order laid down applies in general to parallel intergrowths of allied minerals; thus when augite is intergrown with ægirine or hornblende the former mineral forms the kernel of the complex crystal and the latter the outer shell; when a plagioclase crystal consists of successive layers of different compositions the layers become progressively more acid from the center to the margin.

“Certain constituents having variable relations are omitted from the foregoing list. Thus nepheline (elæolite) and sodalite belong to group 3, but may crystallize out either before or after the feldspar.”[157]

OPTICAL SCHEME.

INTRODUCTION.

The scheme is designed to furnish the student with a practical method of recognizing the common minerals in rock sections.

The arrangement followed has been to group minerals having general optical characters in common, at the same time giving their specific characters so as to make it possible to distinguish one from another. In each rectangle the minerals are arranged in order of their indices of refraction.

A tabulation of the minerals, with a list of optical characters appended, is of aid to the skilled investigator, but of very little assistance to the beginner.

The more common minerals, or those which are important petrographically, are printed in heavy-faced type; the minerals of less importance in small capitals.

ABBREVIATIONS AND CONVENTIONS USED.

A. = Amorphous.

I. = Isometric system.

T. = Tetragonal system.

O. = Orthorhombic system.

M. = Monoclinic system.

Tri. = Triclinic system.

H. = Hexagonal system.

M(H). = Monoclinic, with hexagonal form or characters, as in the case of biotite.

■ = At right angles to.

El. = Elongation.

Ex. = Extinction.

■ Ex. = Parallel extinction, as when the crystals extinguish parallel to cleavage lines or crystal edges. Extinction which is symmetrical to intersecting cleavage lines is also included under this term.

The mean refractive indices are printed in heavy-faced type.

The term “grains” is used to describe not only minerals which occur in typically granular form, but also those which have coarser allotriomorphic form, as elæolite and sodalite in plutonic rocks, such as syenite, etc.

GENERAL RULES FOR USE OF SCHEME.

The division of the scheme into two vertical columns is based on the values of the mean refractive indices, as determined by the “relief” and appearance of the surface. When the refractive index is above 1.60, the relief is fairly well to distinctly marked and the surface rough to very rough, depending on the value of the index.

Most of the rock-forming minerals with indices below 1.60 show no relief and a smooth surface, except in the case of a few of the rarer minerals (mostly isometric), which have very low indices and hence rough surface.

Mistakes may easily be made in the case of minerals near the limit; but practice and the use of the Becke test should soon make possible the classification into the two groups suggested by the scheme, and the appended descriptions will help to check errors.

When an unknown mineral lies adjacent to one that is known, use the Becke test for obtaining the relative refractive index of the unknown mineral; focus sharply on the line of contact between the known and unknown minerals,[158] then raise the objective slightly and the “bright line” will appear on the side of the mineral having the higher index. The method of Schrœder van der Kolk may also be employed, see p. 22.

The horizontal divisions of the scheme depend on the relative strength of the double refraction based on the observed interference colors. These colors to be of use in classification must be correctly recognized. The lower and middle colors of the 1° order, from bluish-gray through white to yellow, are easily known. The bright red, blue, green, etc., colors of the 1°, 2° and 3° orders can also be differentiated without trouble from the very high order colors (4° and above), which are essentially white in tone with no decided color tint.

When confusion arises, the exact order of the color can be determined by a quartz wedge, as given on p. 35. Furthermore, a ¼ undulation mica plate serves to quickly distinguish between the 1° order white and the practically colorless, high order tint of calcite, titanite, etc.; as after the insertion of the test-plate the 1° order white suffers a marked change in color, while the very high order (practically white) tint shows no appreciable change.

In the determination of these interference colors care must be given to considerations of orientation and thickness. The section must give the maximum interference color of all the obtainable sections of the mineral in the rock section. Such sections will be parallel to the _■_ axis in the uniaxial minerals and to the axial plane in the biaxial minerals; and will, therefore, in convergent light never show the emergence of an optic axis or bisectrix. Crystal “form,” cleavage, pleochroism, etc., may at times aid in the selection of these sections. The thickness of the section must also be considered, and it is well in all cases to pick out some known mineral in the section, as quartz, and note its maximum interference color. Knowing how this varies from the color given by the scheme for a section 0.03 mm.[159] in thickness, due allowance can be made for a like variation in the colors given by the other minerals. In the case of minerals with strong absorption the interference colors may not be noticeable on account of the absorption of parts of the light.

Under the subhead of pleochroism, the vibration direction of the ray of a definite color is given and not the direction of transmission of that ray.

The interference figures in convergent light increase in clearness and distinctness with the strength of the double refraction. In uniaxial crystals sections at right angles to the optic axis, _i. e._, sections which remain dark during a revolution between crossed nicols, show the best interference figures. In biaxial crystals the most characteristic interference figures are shown by sections at

right angles to the acute bisectrix.

Crystal sections which are too small do not give very satisfactory interference figures with convergent light.[160]

Any scheme, however designed, makes a more or less arbitrary classification of the minerals, and when in doubt it is always safer to look for the mineral on both sides of the scheme line.

The rarer minerals are not included in this scheme, so when the determination of a mineral is uncertain or not positive recourse should be had to more elaborate tables.

Corrections for Indices of Refraction (mean) in Table on p. 142: Corundum 1.766; Tourmaline 1.674; Tourmaline (precious) 1.633; Dolomite 1.622; Scapolite (Meionite) 1.584; Scapolite (Marialite) 1.551; Calcite 1.601.

Corrections for mean indices of refraction in Scheme (insert folder): Scapolite 1.551 to 1.584; Calcite 1.601 and transfer to Dolomite rectangle; Dolomite 1.622; Corundum 1.766; Tourmaline 1.633 to 1.674.

Footnote 1:

Often called a direction of maximum elasticity, c′ being a direction of minimum elasticity.

Footnote 2:

Rosenbusch's _Microskopische Physiographie_, p. 156.

Footnote 3:

For a more complete discussion of optics, in connection with Optical Mineralogy, the student is referred to A. J. Moses' _Characters of Crystals_, p. 85, et seq.; Moses' & Parsons' _Mineralogy, Crystallography and Blowpipe Analysis_, Chap. XVI., 4th Ed., 1909; Miers' _Mineralogy_, 1902; L. Fletcher's _Optical Indicatrix_, etc., 1892; Groth's _Physikalische Krystallographie_, 3d Ed.; Rosenbusch's _Mikroskopische Physiographie_, 4th Ed. and Iddings' _Rock Minerals_, 1911.

Footnote 4:

The electromagnetic theory of light is now very generally held, but, whatever may be the recurrent change of state to which light is really due, the principles of wave motion furnish a satisfactory geometric description of optical phenomena.

Footnote 5:

These sections are supposed to have plane parallel faces, such being the case in ordinary practice, and to be examined with parallel perpendicularly incident light.

Footnote 6:

It is interesting to remember in this connection that in the isometric system there is also the greatest possible symmetry of "form."

Footnote 7:

A. J. Moses, _Characters of Crystals_, pp. 85–97.

Footnote 8:

For this branch of optical physics, see A. J. Moses, _Characters of Crystals_, pp. 97–100.

Footnote 9:

This can be demonstrated by using a nicol and a plate of calcite which shows a double image. If the nicol is held between the calcite plate and the observer's eye it can be so adjusted that only one image is seen. If now the nicol is revolved 90° the first image will disappear and the other image alone will be seen.

Footnote 10:

In some cases a peculiar form of double refraction does take place parallel to this direction, as in the circular polarization of quartz and cinnabar; but in very thin sections these results are not noticed and can be disregarded.

Footnote 11:

A. J. Moses, _Characters of Crystals_, pp. 98, 99.

Footnote 12:

The terms axes of elasticity are commonly used for these principal vibration directions in text-books on petrography.

Footnote 13:

Instead of ω and ε, for convenience in tables, etc., α and γ are used, denoting the indices of refraction of the rays traversing the crystal with greatest and least velocity respectively, without regard as to which is the _O_ or _E_ ray. A good reason for this convention is that the symbol $(\gamma - \alpha)$ is used to express in decimals the relative strength of the double refraction of a crystal, whether uniaxial or biaxial. γ is always greater than α.

Footnote 14:

For most cases in observations with white light the “optics axes” may be regarded as approximately fixed in position.

Footnote 15:

Often spoken of as: a, the axis of maximum; b, the axis of intermediate, and c, the axis of minimum elasticity.

In the more recent American text-books on Optical Mineralogy by Iddings, Winchell and Phillips a is denoted by _X_, b by _Y_ and c by _Z_.

Footnote 16:

For a short historical sketch of the use of the microscope in connection with Petrology, see G. H. William’s pamphlet, _Modern Petrography (Monographs of Education)_, Boston, 1886. For detail description and adjustments, see _Methods of Petrographic-Microscopic Research_, F. E. Wright, 1911, pp. 11, 61.

Footnote 17:

For description of the ordinary microscope, eye-pieces, objectives, magnification, etc., see _Manipulation of the Microscope_, by Ed. Bausch.

Footnote 18:

Text Book of Mineralogy, by E. S. Dana, 1898 Ed., p. 176.

Footnote 19:

It is convenient to assume that the vibrations of the polarized light are taking place in this plane, called the “plane of vibration,” but all the phenomena caused by polarized light could be also explained on the assumption that the vibrations were taking place at right angles to this plane.

Footnote 20:

This condensing lens must be removed when very low power objectives are used.

Footnote 21:

Some microscopes are provided with adjusting screws bearing on the frame holding the objective, which can then be accurately centered to the axis of rotation of the stage.

Footnote 22:

In the Seibert microscope use objective No. 00 for the first general study of a rock section, No. II for general use and No. V for observations with convergent light. In the Fuess microscope use objective No. 4 for general use and No. 7 for convergent light tests. In the case of an English microscope a 1″ to ¾″ objective is used for general purposes and a ¼″ to ■″ for observations with convergent light.

Footnote 23:

See pp. 33 and 34.

Footnote 24:

In some microscopes the analyzer is in the form of a “cap” nicol, arranged to be fitted over the top of the eye-piece, and not introduced in the microscope tube as shown here. This form is not so convenient, as the “cap” nicol must be set by hand every time it is desired to make observations with crossed nicols. But at the same time it avoids any possible refocusing which may be

necessary when the other type of analyzer is introduced in the tube.

Footnote 25:

When accurate adjustments are possible of the vibration planes of the nicols and the cross-wires parallel to these vibration planes, reference should be made to _Methods of Petrographic-Microscopic Research_, p. 61, 1911, Fred. E. Wright.

Footnote 26:

In the Seibert microscope eye-piece No. 0 is used for most purposes. Other eye-pieces, Nos. 1 and 2, with cross-wires, are used for different degrees of magnification, and one eye-piece, No. 3, without cross-wires, is provided to be used in connection with an eye-piece micrometer.

Footnote 27:

With the Seibert microscope, Fig. 2, the No. 0 eye-piece and the No. II objective will prove most satisfactory for the following tests. With the Fuess microscope use No. 4 objective. With an English microscope use an ordinary eye-piece and a 1″ or ¾″ objective.

Footnote 28:

Twins may be recognized just as in macroscopic specimens, and zonal structure noticed if the zones differ in color. When a colorless mineral is surrounded by other colorless minerals, of about the same index of refraction, its outline is often best brought out by observation between crossed nicols.

Footnote 29:

The term “Anhedron,” meaning without planes, has been suggested by L. V. Pirsson to describe in rocks the crystal fragments which have no plane faces, as, for example, the augites of augitic rocks. _Science_, Jan. 10, 1896, p. 49.

Footnote 30:

Partial resorption and recrystallization may produce a border of secondary minerals, surrounding the original crystal.

Footnote 31:

The surfaces of all minerals in sections are more or less rough, but this roughness is only made visible when there is a marked difference between the indices of refraction of the minerals, and the index of refraction of the balsam in which the minerals are embedded. The index of refraction of balsam is about 1.54, so it is only when the mineral has a higher or lower index of refraction that its surface appears rough. When internal structure is to be studied, the crystal should be surrounded by a fluid of nearly the same index of refraction as that of the crystal, and when the exterior of the crystal is to be studied, then a fluid should be used with a very different index of refraction.

Footnote 32:

The Seibert microscope has a very convenient and quick lowering adjustment, by means of the lever _d_, for making this test. For convenience the lower nicol and condensing lens are generally left in place below the stage of the microscope, as polarized light serves as well for these investigations as ordinary light. An additional advantage in this arrangement is that the condensing lens is always ready for the “relief” test and the lower nicol for the pleochroism test; but it must be remembered that the polarizer or lower nicol cuts out one half of the light, which comes to it from the reflector, and this loss is important when high power objectives are to be used. When very low power objectives are used, the condensing lens must be removed.

Mem. de l’Acad., Paris, 1767–68.

Footnote 34:

Min. Mag., Vol. I., p. 193; Vol. II., p. 1.

Footnote 35:

Sitzungsberichte der k. k. Akad. der Wiss., Wien, 1893, I Abt., p. 358. Translation by L. McI. Luquer in _School of Mines Quarterly_, Vol. XXIII., Jan., 1902, No. 2, p. 127. Review by Viola in _Min. Pet. Mitt._, Vol. 14, p. 554. _Methods of Petrographic-Microscopic Research_, F. E. Wright, 1911, p. 95.

Footnote 36:

Most of the petrographical microscopes carry over the polarizer a convex lens the effect of which is to widen the illuminating cone and hence make less visible this phenomenon.

Footnote 37:

In Seibert student microscope, No. II _a_, use next to smallest light-stop. Some of the Fuess microscopes are supplied with an iris-blende for limiting the cone of light.

Footnote 38:

In Seibert microscope use No. V, not sufficiently marked results being obtained with No. II.

Footnote 39:

See Viola's diagram, _Minn. Pet. Mitt._, Vol. XIV., p. 556.

Footnote 40:

Seibert, No. II. Fuess, No. 4.

Footnote 41:

Kurze Anleitung zur mikrosk. _Krystallbestimmung_, Wiesbaden, 1898, and _Tabellen zur mikrosk._ _Bestimmung_, etc., Wiesbaden, 1900. _Methods of Petrographic-Microscopic Research,_ F. E. Wright, 1911, p. 93.

This method is particularly favorable for the accurate determination of the refractive indices of small isolated fragments or grains, by using liquids of known indices. In this case a bright line appears on the "near" edge and a dark line on the "far" edge if the grain has a higher index than the liquid. The reverse occurs when the index is lower than the liquid. When the index is the same (using white light) the "far" edge is blue and the "near" edge red and also the contours about disappear.

F. Krantz, of Bonn, furnishes a series of 21 liquids in small bottles, with indices from 1.447 to 1.83.

The indices of a few convenient liquids are: water, 1.34; alcohol, 1.36; glycerine, 1.41; olive oil, 1.47; nut oil, 1.50; clove oil, 1.54; aniseed oil, 1.58; almond oil, 1.60; cassia oil, 1.63; monobromnapthalene, 1.65; methylene iodide, 1.75.

Footnote 42:

Crystals that have two good cleavages often develop so that the direction of elongation is parallel to the intersection of the two cleavages, while in the case of crystals with one good cleavage the tendency seems to be towards a tabular habit parallel to the cleavage.

Footnote 43:

Harker's _Petrology for Students_, p. 306.

Footnote 44:

The lower nicol is generally so adjusted that its plane of vibration is parallel to the north and south cross-wire in the eye-piece. This adjustment can be tested by means of a section of biotite, showing cleavage cracks. When the plane of vibration of the polarizer is parallel to the N. and S. cross-wire in the eye-piece, the biotite section becomes almost dark when its cleavage cracks are parallel to the same cross-wire. The upper nicol, or analyzer, must, of course, be removed during this test. This method is more convenient than taking the nicol out of its frame, in order to ascertain its plane of vibration (the direction of its shorter diagonal).

Footnote 45:

Although the “absorption directions” may not necessarily coincide with the principal vibration directions in Monoclinic and Triclinic crystals; still for convenience the absorption colors are usually given for the light rays vibrating parallel to these principal vibration directions.

Footnote 46:

In the Fuess and Seibert microscopes the analyzer or upper nicol is so fitted that it slides in and out of the tube of the microscope with its plane of vibration always at right angles to the plane of vibration of the polarizer or lower nicol.

Footnote 47:

Footnote 48:

Iddings’ _Rock Minerals_, 1911, p. 172.

Footnote 49:

These sections always contain the principal vibration directions _a_ and _c_.

Footnote 50:

Methods of Petrographic-Microscopic Research, F. E. Wright, 1911, p. 101.

Footnote 51:

A chart of interference colors can be obtained from Baudry et Cie, Paris, and is also published in _Les Minéraux des Roches_, by Lévy and Lacroix, _Rock Minerals_ (1911), by Iddings and in Rosenbusch’s _Mikroskopische Physiographie_.

Footnote 52:

Iddings’ _Rock Minerals_, 1911, pp. 141, 183.

Footnote 53:

Methods of Petrographic-Microscopic Research, F. E. Wright, 1911, p. 132.

Footnote 54:

The ¼ undulation mica plate consists of a thin cleavage of mica on which is marked _c_, the vibration direction of the slower ray, which in mica is the line joining the “optic axes.” The thickness is such that the slower ray is ¼ wave-length behind the faster and the interference color is a bluish-gray. The gypsum plate is a thin cleavage of gypsum, on which is usually marked a, the vibration direction of the faster ray. The chosen thickness is such as to produce the red interference color of the 1° order.

Footnote 55:

The test-plates are generally introduced in the slot _k_, in a microscope of the Seibert type, or if a cap-nicol is used in a slot below this. In case no provision is made by the instrument maker for these test-plates, the regular analyzer is left out of the tube, and a simple nicol prism is used as an analyzer and is held by the observer over the eye-piece. Care must be taken to have the plane of vibration of this nicol at right angles to that of the polarizer, and to leave sufficient room for the introduction, by hand, of the test-plate between the eye-piece and the nicol. With care the plates can be introduced with sufficient accuracy to make the test practical.

Footnote 56:

A scale or chart of interference colors, or the interference color diagram, should be before the observer in order to avoid any mistakes as to whether the new color is higher or lower in the scale.

Footnote 57:

The quartz wedge is cut so that one of its faces is exactly parallel to the _■_ axis (hence also parallel to the _c_ vibration direction) while the other face makes a very small angle with it. The direction _c_ is marked on the wedge.

Footnote 58:

Described under next test.

Footnote 59:

In applying this rule count the 1° order white as green and the 1° order gray as blue.

Footnote 60:

A. J. Moses, _Trans. N. Y. Acad. Sci._, Vol. XVI., p. 55, Jan., 1897.

Footnote 61:

E. von Federow, _Zeit. f. Kryst., etc._, Vol. XXXV., p. 340, 1895.

Footnote 62:

After the first rough determination of the phase difference by the mica wedge, the more exact phase difference can be obtained by the aid of a good color chart or diagram, see end of book.

Footnote 63:

It is not safe to use minerals near the edge of the section, as the thicknesses are apt to be unequal.

Footnote 64:

See at end of appendix.

Footnote 65:

In this way eliminate, so far as possible, the effect of the orientation of the mineral section.

Footnote 66:

The different mineral sections are all supposed to have the same thickness throughout the rock section.

Footnote 67:

Harker's _Petrology for Students_, 1895, p. 14.

Footnote 68:

Iddings' _Rock Minerals_, pp. 153, 173. Moses' _Characters of Crystals_, p. 115.

Footnote 69:

In the Seibert microscope use No. V objective, in Fuess microscope No. 7 objective, and in English microscopes a ¼″ or ■″ objective.

Footnote 70:

Each convergent ray will have its vibration direction either in or at 90° to the plane through the ray and the optic axis. Hence all rays vibrating parallel to the vibration planes of both nicols will be completely cut out. As the section is rotated new rays successively come into these positions, so the same effect is maintained.

Footnote 71:

In the Seibert microscope there is a little slot _k_ for this purpose just above the objective.

Footnote 72:

The optical character may also be determined in parallel light by proving _■_ = c(+), _■_ = a(–). The optical character of the principal zone or the sign of the elongation is often given in tables. This optical character or sign is (+) when the principal zone axis or the direction of elongation is parallel to c and (–) when parallel to a.

Footnote 73:

Iddings' _Rock Minerals_, 1911, p. 172.

Footnote 74:

This assumes the optic axes for different colors to emerge about at the same points. If there is marked "dispersion" the black bands and hyperbolas may be rainbow-hued, as with titanite.

Footnote 75:

The interference figure, perpendicular to the _obtuse bisectrix_, would be of the same type with a larger axial angle. Ordinarily this figure would not come within the limits of the field of view of the microscope. Confusion may arise, however, but in a section perpendicular to the acute bisectrix the cross dissolves more slowly into the hyperbolas than in the case of a section perpendicular to the obtuse bisectrix. At times it may be necessary to measure the axial angle to be sure. When, however, the mineral is known, the section perpendicular to the acute bisectrix can be recognized, because if the mineral is optically positive the trace of the axial plane is parallel to a and if negative parallel to c.

Footnote 76:

For construction of quartz wedge, see p. 34.

Footnote 77:

The wedge can be introduced in either of the several ways described for the introduction of the test-plates on p. 33.

Footnote 78:

For methods of measuring the axial angle, see _Methods of Petrographic-Microscopic Research_, F. E. Wright, 1911, p. 147.

For convenience in many cases only 2_E_ is recorded, as then an indication is given as to whether the axial angle is visible with an ordinary microscope (arranged for observation with convergent light for interference figures). If 2_E_ is very large the axial angle can only be observed by covering the section with some transparent, strongly refracting fluid. For the Seibert microscope with objective V the limit for good results is about 2_E_ = 90°–100°.

Footnote 79:

For dispersion, etc., see A. J. Moses' _Characters of Crystals_, p. 140.

Footnote 80:

The system of crystallization of leucite has been the subject of much discussion. Its habit is isometric. The consensus of opinion seems to be that leucite crystallizes in the isometric system, but that the isometric molecular arrangement, at least of the larger crystals, cannot exist for the temperature and pressure at the earth's surface. Hence molecular displacement takes place, giving rise to a more or less complicated apparent twinning, and optical anomalies are noticed. The isotropic character returns if the section is heated to 500° C. Iddings' _Rock Minerals_, p. 249, 1911.

Footnote 81:

C. W. Knight, _Canad. Rec. of Sci._, IX, No. 5. 265.

Footnote 82:

The interference colors of all minerals here recorded are those given by sections 0.03 _mm._ in thickness (very thin sections).

Footnote 83:

Shown by Mügge, Joly, etc., to be caused by radiations emanating from U, Th, R, etc. Iddings' _Rock Minerals_, 1911, p. 189.

Footnote 84:

Iddings' _Rock Minerals_, 1911, p. 392.

Footnote 85:

See page 31.

Footnote 86:

R. D. Irving, _Am. Jour. Sci._, June, 1883.

Footnote 87:

Granites of the central Alps, where the calcite crystals are intergrown with quartz.

Footnote 88:

The minerals Nephelite, leucite, sodalite (haüynite and noselite) and melilite are often grouped together under the name "_feldspathoides_"; on account of their relation in rocks being equivalent to that of the feldspars.

Footnote 89:

Oriented in conformity to the intergrowth with augite, etc., (010) and (100) are reversed.

Footnote 90:

For other alteration processes, see Iddings' _Rock Minerals_, p. 380.

Footnote 91:

May be difficult to determine in the case of prism zone sections, showing large extinction angles.

Footnote 92:

See p. 88.

Footnote 93:

Iddings' _Rock Minerals_, p. 456, 1911.

Footnote 94:

Depending on whether the axial plane is parallel or at right angles to the clino pinacoid (010) (the plane of symmetry), we have micas of the second (biotite) or first order (muscovite).

Footnote 95:

The distinction between zoisite α and β (essentially orthorhombic, but may be composite triclinic twins) and clinozoisite (monoclinic close to orthorhombic) depends on differences in position of plane of optic axes; axial figures shown by cleavage plates; dispersion; anomalous interference colors; etc. See Weinschenk's _Die Gesteinbildenden Mineralien_, p. 83. 1901.

Footnote 96:

Test not easily made on account of the very high order interference colors, resulting from the strong double refraction.

Footnote 97:

See under quartz, p. 63.

Footnote 98:

Iddings' _Rock Minerals_, p. 208, 1911.

Footnote 99:

On account of the weak double refraction the interference figures are not very sharp or well defined in thin sections. In most cases only the black hyperbolas are seen, without any colored curves.

Footnote 100:

By heating feldspar crystals the axial angle decreases to 0° and then increases in the plane of symmetry (at right angles to its former position). On cooling the axial angle returns to its former position if the temperature has not exceeded 500° C. If the temperature has been 600°–1000° C. for some time the axial angle will not return to its former position. This fact may give some clew as to the temperature at which the feldspar crystals formed.

Footnote 101:

This change to kaolin or clay in granite is called by Dolomieu "_La maladie du granit_."

Footnote 102:

See p. 31.

Footnote 103:

Hatch's _Introduction to the Study of Petrology_, p. 33.

Footnote 104:

J. W. Judd, _Geol. Mag._ [3], Vol. VI, p. 243, 1889.

Footnote 105:

The plagioclases have rather a complex composition; but may be regarded as forming a series from the composition $NaAlSi_{3}O_{8}$(Ab) to the composition $CaAl_{2}Si_{2}O_{8}$(An), consisting for the most part of isomorphous mixtures of these types, with some replacement by $KAlSi_{3}O_{8}$. The compositions of only a few of the common plagioclases are given above.

Footnote 106:

The lath-shaped feldspars, moulding the augite, give to diabases the so-called "ophitic" structure, Fig. 12. The peculiarity of this structure is that the feldspars crystallized before the augite, which is contrary to the usual order of formation.

Footnote 107:

For the positions of the optic axes, bisectrices, etc., relative to the cleavage plates of the different plagioclases, see Iddings' _Rock Minerals_, p. 222, 1911.

Footnote 108:

Die Gesteinsbildenden Mineralien (with tables), E. Weinschenk, Freiburg, 1901. _Étude sur la Détermination des Feldspaths dans les Plaques Minces_, Michel Lévy, Paris, 1894; and _The Determination of the Feldspars_, N. H. Winchell, _Am. Geol._, Vol. XXI, No. 1, 1898. Iddings' _Rock Minerals_, Wiley & Sons, 1911. _Étude sur la Détermination des Feldspaths_ (troisième fascicule), Michel Lévy, Paris, 1904.

Footnote 109:

Glass models of the feldspars (size 20 × 10 cm.) by F. Krantz, Bonn. Diagrams, showing optical orientation in the plagioclases, in _Die Gesteinsbildenden Mineralien_, E. Weinschenk, p. 133, 1901.

Footnote 110:

For this method of investigation little cleavage flakes or plates can often be obtained from the crushed mineral, but, on account of Albite twinning, plates are more apt to be obtained parallel to the twinning plane than to the best basal cleavage. If a fragment with only one cleavage surface is obtained, it must be cemented to a glass by this surface and ground down to a thin section with parallel sides.

Footnote 111:

This test is only possible when suitable sections of the given feldspar in the rock section can be found. The method, however, can be used with great accuracy with the aid of some form of apparatus for properly orienting the section. See “Klein’s Apparatus for the Orientation of Thin Sections,” _Sitzungsber. Berlin. Akad._, 1895, 1151; (also in _N. Y. Acad. Sci._, Vol. XVI, p. 51, 1897); and Von Federov’s “Universal Table,” _Zeit. für Kryst, etc._, Vol. XXV., p. 351.

Footnote 112:

In the determination of feldspar microlites it is well to remember the following facts: “Microcline is rarely, or never, seen in the condition of microlites, while the associations of labradorite and albite are so different that there is little danger of confounding them. Labradorite is the commonest product of the consolidation of the basic eruptives, and albite almost invariably results from metamorphism, frequently from the contact of igneous rocks on the calcareous clastics.” N. H. Winchell, Determination of the Feldspars, _Am. Geol._, Vol. XXI, No. 1, p. 33, 1898.

Footnote 113:

These methods (both 2 and 3) are often not applicable on account of the tendency of the crystals in an effusive rock to parallel orientation, which may be so marked that the rock section does not show any favorable sections of the plagioclase.

Footnote 114:

These extinction angles, as well as those previously given, are those of only a few type feldspars of definite composition. As the composition varies through a long series, so the extinction angle changes, one being a function of the other.

For a complete list of compositions and related extinction angles, see Iddings’ _Rock Minerals_ and Lévy & Lacroix’s _Les Minéraux des Roches_.

PREFACE

MY subject is the tragedy of the Western world-view._(_1_)_

While still a student I was surprised to find the history of thought always written merely as a history of philosophical systems, never as the history of man’s effort to arrive at a world-view. Later, when reflecting on the current of civilization in which I found myself living, I was struck by the strange and inexorable connexions which exist between civilization and our view of the world as a whole. Next I felt a still stronger compulsion to put to Western thought the question what it has been aiming at, and what result it has reached in the matter of world-view. What is there left of the achievements of our philosophy when it is stripped of its tinsel of learning? What has it to offer us when we demand from it those elemental ideas which we need if we are to take our position in life as men who are growing in character through the experience given by work?

So I came to an unsparing reckoning up with Western thought. I recognized and admitted that it has sought for that world-view from which alone a deep and comprehensive civilization can come. It wanted to reach a position [pg vi] of world- and life-affirmation and on that foundation lay down that it is our duty to be active, to strive for progress of all kinds, and to create values. It wanted to reach an ethical system and on that foundation lay down that for the sake of serviceable activity we have to place our life at the service of ideas and of the other life around us.

But it did not succeed in grounding its world- and life-affirming ethical world-view convincingly and permanently in thought. Our philosophy did nothing more than produce again and again unstable fragments of the serviceable world-view which hovered before its mind's eye. Consequently our civilization also remained fragmentary and insecure.

It was a fatal mistake that Western thought never admitted to itself the unsatisfying result of its search for a stable and serviceable world-view. Our philosophizing became less and less elemental, losing all connexion with the elementary questions which man must ask of life and of the world. More and more it found satisfaction in the handling of philosophic questions that were merely academic, and in an expert's mastery of philosophical technique. It became more and more the captive of secondary things. Instead of real music it produced again and again mere bandmaster's music, often magnificent stuff of its kind, but still only bandmaster's music.

Through this philosophy which did nothing but philosophize instead of struggling for a world-view grounded in thought and serviceable for life, we came to be without any world-view and therefore without any civilization.

Signs of an awakening of thought on this point are beginning to be visible. It is admitted here and there that philosophy must again try to offer a world-view. This is generally expressed by saying that people are encouraging it to venture once more on "metaphysics," that is to put forward definitive views about the spiritual nature of the world, whereas hitherto it has been occupied with the classification of scientific facts and in cautious hypotheses.

Not only in philosophy, but in thought generally this [pg vii] awakening of the need for a world-view expresses itself as a need for "metaphysics." Fantastic systems of "metaphysics" are sought for and offered. Individuals who believe that they have at their disposal peculiar psychic experiences, and assert that with their aid they can look behind the actual nature of phenomena, come forward as bringers of a world-view.

But neither the cautious academic, nor the much-claiming fantastic "metaphysics," can really give us a world-view. That the road to a world-view leads through "metaphysics" is a fatal error which has already enjoyed too long a span of life in our Western thought. It would be tragic if we renewed its vigour just now, when we are faced by the necessity of working our way out of that lack of world-view in which our misery, both spiritual and material, is grounded. No further wandering along the traditional roads that lead nowhere can save us, whether we advance as the successors of our fathers or on adventurous lines of our own. Only in a deep conception of and experience in the problems of world-view is there for us any possibility of advance.

That is why I am undertaking what has never been attempted in this way before, viz. so to pose the problem of the Western world-view as to make the Western search for a world-view come to a halt and take account of itself. There are two points on which it must be clear before it proceeds to further exertion. The first is the overwhelming importance in the search for a world-view of the quality of the world-view sought. What is it that we want? We want to find the world- and life-affirmation and the ethical system which we need for that serviceable activity which gives our life a meaning, based on such thought about the world and life as finds a meaning in them also. If our search for a world-view is once thoroughly permeated by the recognition that everything turns upon these two fundamental questions, it is thereby saved from betaking itself to by-paths, thinking that by some happy disposition of fortune it can reach its goal along them. It will then [pg viii] not search for a "metaphysic," thinking by means of it to reach a world-view, but it will search for a world-view and accept with it anything "metaphysical" that may turn up. From every point of view it will remain elemental.

The second task which the conscious search for a world-view must not shirk, is the consideration of what is the real and ultimate nature of the process by which it has hitherto attempted to secure that serviceable world-view which hovered before it. Reflexion on this is necessary that it may make up its mind whether further advance along the road it has hitherto followed gives any prospect of success. Our philosophy ought to have been philosophizing long ago about the road along which it was going in search of a world-view. It never did so, and therefore was always running uselessly round and round in a circle.

The process by which Western thought has hitherto sought for a world-view is doomed to be fruitless. It consisted simply in interpreting the world in the sense of world- and life-affirmation, that is, in attributing to the world a meaning which allowed it to conceive the aims of mankind and of individual men as having a meaning within it. This interpretation is acted upon by all Western philosophy. A few thinkers who venture to be un-Western and resolutely allow world- and life-negation and ethics to be made subjects of discussion, are side-currents which do not affect the main course of the river.

That this process followed by Western thought consists in adopting an optimistic-ethical interpretation of the world will not be clear without further explanation, for it is, indeed, not always openly followed. The optimistic-ethical interpretation is often to be found imbedded in the results of investigations into the nature of knowledge; it often appears beneath a veil of “metaphysics”; it is often so delicately shaded that it produces none of its usual effects. It is only when one has clearly grasped the fact that Western thought has nothing else in mind than to establish for itself a world-view based on world- and life-affirmation and ethical in character, that one can realize [pg ix] how in its theory of knowledge, in its metaphysics, and in all its movements generally in the game of life, it is guided, consciously or unconsciously, by the effort to interpret the world in some way or other and in some measure in the sense of world- and life-affirmation and of ethics. Whether in this attempt it goes to work openly or secretly, skilfully or unskilfully, honourably or craftily, does not matter. Western thought needs this interpretation that it may be able to give a meaning to human life. Its view of life is to be a result of its view of the world. No other course was ever taken into consideration by it.

But this awakening of Western thought will not be complete until that thought steps outside itself and comes to an understanding with the search for a world-view as this manifests itself in the thought of mankind as a whole. We have too long been occupied with the developing series of our own philosophical systems, and have taken no notice of the fact that there is a world-philosophy of which our Western philosophy is only a part. If, however, one grasps philosophy as being a struggle to reach a view of the world as a whole, and seeks out the elementary convictions which are to deepen it and give it a sure foundation, one cannot avoid setting our own thought face to face with that of the Hindus and Chinese in the Far East. The latter looks strange to us because much of it has remained even till now naïve and embodied in myth, while in other parts again it has spontaneously advanced to refinements of criticism and to artificialities. But this does not matter. The essential thing is that it is a struggle for a world-view: the form it takes is a secondary matter. Our Western philosophy, if judged by its own latest pronouncements, is much naïver than we admit to ourselves, and we fail to perceive it only because we have acquired the art of expressing what is simple in a learned way.

Among the Hindus we encounter the world-view which is based on world- and life-negation, and the way in which it grounds itself in thought is calculated to leave us not knowing what to make of our prejudice in favour of world- [pg x] and life-affirmation, which, as Westerners, we are inclined to assume as something more or less self-evident.

The attraction and tension which in Hindu thought govern the relations between world- and life-negation and ethics, afford us glimpses into the problem of ethics for which Western thought offers us no comparable opportunities.

Nowhere, again, has the problem of world- and life-affirmation, both in itself and in its relation to ethics, been felt in so elemental and comprehensive a fashion as in Chinese thought. Lao-tse, Chwang-tse, Kung-tse (Confucius), Meng-tse, Lie-tse, and the rest, are thinkers in whom the problems of world-view with which our Western thought is wrestling, encounter us in a form, strange indeed, but compelling our attention.

Discussing these problems with them means discussing them with ourselves also.

That is why I bade our search for a world-view seek to reach clear ideas about itself, and come to a halt in order to fix its attention on the thought of mankind as a whole.

My solution of the problem is that we must make up our minds to renounce completely the optimistic-ethical interpretation of the world. If we take the world as it is, it is impossible to attribute to it a meaning in which the aims and objects of mankind and of individual men have a meaning also. Neither world- and life-affirmation nor ethics can be grounded on what our knowledge of the world can tell us about the world. In the world we can discover nothing of any purposive evolution in which our activities can acquire a meaning. Nor is the ethical to be discovered in any form in the world-process. The only advance in knowledge that we can make is to describe more and more minutely the phenomena which make up the world and their course. To understand the meaning of the whole—and that is what a world-view demands—is for us an impossibility. The last fact which knowledge can discover is that the world is a manifestation in every way puzzling, of the universal will-to-live.

[pg xi]

I believe I am the first among Western thinkers who has ventured to recognize this crushing result of knowledge, and who is absolutely sceptical about our knowledge of the world without at the same time renouncing with it belief in world- and life-affirmation and ethics. Resignation as to knowledge of the world is for me not a hopeless fall into a scepticism which leaves us to drift about in life like a derelict vessel. I see in it that effort of honesty which we must venture to make in order to arrive at the serviceable world-view which hovers within sight. Every world-view which does not start from resignation in regard to knowledge, is artificial and a mere fabrication, for it rests upon an inadmissible interpretation of the world.

When once thought has become clear to itself about the relation in which world-view and life-view stand to each other, it is in a position to reconcile resignation as to knowledge with adherence to world- and life-affirmation and ethics. Our view of life is not dependent on our view of the world in the way that uncritical thought imagines it to be. It does not wither away if it cannot send its roots down into a corresponding world-view, for it does not originate in knowledge although it would like to base itself thereon. It can safely depend upon itself alone, for it is rooted in our will-to-live.

World- and life-affirmation and ethics are given in our will-to-live, and they come to be clearly discerned in it in proportion as it learns to think about itself and its relation to the world. The rational thought of other times aimed at getting to know the world, and at being able in that knowledge to conceive of the highest impulses of our will-to-live as purposive in view of the universe and its evolution. But that aim was unattainable. We are not meant to unite the world and ourselves in such harmony with one another. We were naïve enough to assume that our view of life must be contained in our view of the world, but the facts do not justify this assumption. The result is that our thought finds itself involved in a dualism with which it can [pg xii] never finally settle. It is the dualism of world-view and life-view, of knowing and willing.

To this dualism all the problems with which human thought has busied itself ultimately go back. Every fragment of the thought of mankind which has any bearing on man's view of the world—whether in the world-religions or in philosophy—is an attempt to resolve this dualism. It is sometimes softened down, but only to let a unitary, monistic world-view be adopted in its place; at other times it is left current, but is transformed into a drama with a monistic issue.

Innumerable are the expedients which thought used in trying to get rid of dualism. Everything it has undertaken commands respect, even the staggering _naïvetés_ and the meaningless acts of violence to which it committed itself, for it was always acting under the compulsion of an inner necessity: it wanted to rescue a serviceable world-view from the abyss of dualism.

But from this continuous mishandling of the problem no solution could issue capable of satisfying thought. We were to be taken over the abyss on tottering bridges of snow.

Instead of going on bridging this abyss with forced logic and imaginative ideas, we must make up our minds to get to the root of the problem and let it work upon us as it comes straight to meet us in the facts. The solution is, not to try to get rid of dualism from the world, but to realize it as something which can no longer do us any harm. That is possible if we leave behind us all the arts and the unveracities of thought and bow to the fact that, as we cannot harmonize our life-view and our world-view, we must make up our minds to put the former above the latter. The volition which is given in our will-to-live reaches beyond our knowledge of the world. What is decisive for our life-view is not our knowledge of the world but the character of the volition which is given in our will-to-live. The universal spirit meets us in nature as puzzling creative power. In our will-to-live we experience [pg xiii] it within us as volition which is both world- and life-affirming and ethical.

Our relation to the world as it is given in the character of our will-to-live, when this latter seeks to comprehend itself in thought: that is our view of the world. World-view is a product of life-view, not _vice versâ_.

The rational thought of to-day, therefore, does not hunt the phantom of getting to know the world. It leaves knowledge of the world on one side as something unattainable by us, and tries to come to clear ideas about the will-to-live which is within us.

The problem of world-view, then, brought back to facts and tackled by rational thought without assumptions being made, may be put thus: "What is the relation of my will-to-live, when it learns to think, to itself and to the world?" And the answer is: "From an inner compulsion to be true to itself and to remain consistent with itself, our will-to-live enters into relations with our own individual being and with all manifestations of the will-to-live which surround it, that are determined by the sentiment of reverence for life."

Reverence for life, _veneratio vitæ_, is the most direct and at the same time the profoundest achievement of my will-to-live.

In reverence for life my knowledge passes into experience. The unsophisticated world- and life-affirmation which is within me just because I am will-to-live has, therefore, no need to enter into controversy with itself, if my will-to-live learns to think and yet does not understand the meaning of the world. In spite of the negative results of knowledge I have to hold fast to world- and life-affirmation and deepen it. My life carries its own meaning in itself. This meaning lies in my living out the highest idea which shows itself in my will-to-live, viz. the idea of reverence for life. With that for a starting-point I give value to my own life and to all the will-to-live which surrounds me, I persevere in activity, and I produce values.

Ethics grow out of the same root as world- and [pg xiv] life-affirmation, for ethics, too, are nothing but reverence for life. That is what gives me the fundamental principle of morality, viz. that good consists in maintaining, promoting, and enhancing life and that destroying, injuring, and limiting life are evil. Affirmation of the world, which means affirmation of the will-to-live that manifests itself all round me, is only possible if I devote myself to other life. From an inner necessity I exert myself in producing values and practising ethics in the world and on the world even though not understanding the meaning of the world. For in world- and life-affirmation and in ethics I carry out the will of the universal will-to-live which reveals itself in me. I live my life in God, in the mysterious divine personality which I do not know as such in the world, but only experience as a mysterious Will within myself.

Rational thinking which is free from assumptions ends therefore in mysticism. To relate oneself in the spirit of reverence for life to the multiform manifestations of the will-to-live which together constitute the world is ethical mysticism. All profound world-view is mysticism, the essence of which is just this: that out of my unsophisticated and naïve existence in the world there comes, as a result of thought about self and the world, spiritual self-devotion to the mysterious infinite Will which is continuously manifested in the universe.

This world-affirming, ethical, active mysticism has always been hovering as a vision before Western thought, but the latter could never adopt it because in its search for a world-view it always turned into the wrong road of optimistic-ethical interpretation of the world, instead of reflecting directly on the relation which man assumes to the world under the inner compulsion of the deepest characterisation of his will-to-live.

From my youth onwards I have felt certain that all thought which thinks itself out to an issue ends in mysticism. In the stillness of the primæval forest in Africa I have been able to work out this thought and give it expression.

I come forward therefore with confidence as a restorer [pg xv] of that rational thought which refuses to make assumptions. I know indeed that our time will have absolutely no connexion with anything that is in any way rationalistic, and would like to know it renounced as an aberration of the eighteenth century. But the time will come when it will be seen that we must start again where that century came to a stop. What lies between that time and to-day is an intermezzo of thought, an intermezzo with extraordinarily interesting and valuable moments, but nevertheless an unhappy and fatal one. Its inevitable end was our sinking into a condition in which we had neither world-view nor civilization, and which contains in itself all that spiritual and material misery in which we languish.

The restoration of our world-view can come only as a result of inexorably truth-loving and recklessly courageous thought. Such thinking alone is mature enough to learn by experience how the rational, when it thinks itself out to a conclusion, passes necessarily over into the non-rational. World- and life-affirmation and ethics are non-rational. They are not justified by any corresponding knowledge of the nature of the world, but are the disposition in which, through the inner compulsion of our will-to-live, we determine our relation to the world.

What the activity of this disposition of ours means in the evolution of the world, we do not know. Nor can we regulate this activity from outside; we must leave entirely to each individual its shaping and its extension. From every point of view, then, world- and life-affirmation and ethics are non-rational, and we must have the courage to admit it.

If rational thought thinks itself out to a conclusion, it comes to something non-rational which, nevertheless, is a necessity of thought. This is the paradox which dominates our spiritual life. If we try to come through without this non-rational, the result is views of the world and of life which are without life and without value.

All valuable conviction is non-rational and has an emotional character, because it cannot be derived from [pg xvi] knowledge of the world but arises out of the thinking experience of our will-to-live, in which we stride out beyond all knowledge of the world. This fact it is which the rational thought that thinks itself out to a conclusion comprehends as the truth by which we must live. The way to true mysticism leads up through rational thought to deep experience of the world and of our will-to-live. We must all venture once more

to be “thinkers,” so as to reach mysticism, which is the only direct and the only profound world-view. We must all wander in the field of knowledge to the point where knowledge passes over into experience of the world. We must all, through thought, become religious.

This rational thought must become the prevailing force among us, for all the valuable ideas that we need develop out of it. In no other fire than that of the mysticism of reverence for life can the broken sword of idealism be forged anew.

In the disposition to reverence for life lies enclosed an elementary conception of responsibility to which we must surrender ourselves; in it there are forces at work which drive us to revision and ennoblement of our individual social and political disposition.

It is the disposition to reverence for life, too, which alone is capable of creating a new consciousness of law. The misery prevailing under our political and social condition consists to a great extent in this, that neither jurists nor laity have in their minds a living and direct conception of law. During the age of rational thought there was a search made for such a conception, and effort was made to establish fundamental laws which were held to be given in the nature of man, and to get them generally recognized. Later on, however, this was given up, and laws passed at definite dates displaced natural law. Finally we got to the stage of being satisfied with purely technical law. This was the intermezzo which followed the period of rational thought in the sphere of law.

We have entered on a period in which the feeling for [pg xvii] law is hopelessly bereft of force, of soul, and of sense of moral obligation. It is a period of lawlessness. Parliaments produce with easy readiness statutes which contradict the idea of law. States deal arbitrarily with their subjects without regard to the maintenance of any feeling for law. Those, indeed, who fall into the power of a foreign nation are outlaws. No respect is shown for their natural right to a fatherland, or freedom, or dwelling-place, or property, or industry, or food, or anything else. Belief in law is to-day an utter ruin.

This state of things was in preparation from the moment when the search for the natural conception of law, grounded on rational thought, was given up.

The only thing to be done, then, is to make a new connexion in the sphere of law also, at the point where the thread of the rational thought of the eighteenth century got broken. We must search for a conception of law that is grounded in an idea which grows directly and independently out of a world-view. We have to re-establish human rights which cannot be infringed, human rights which guarantee to each person the greatest possible freedom for his personality in his own national body, human rights which protect his existence and his human dignity against any foreign violence to which he may be subjected.

Jurists have allowed law and the feeling for law to be ruined. They could not help it, however, for there was no idea provided by the thought of the time to which a living conception of law could have anchored itself. In the complete absence of any world-view law collapsed entirely, and it is only out of a new world-view that it can be built up again. It is from a fundamental idea about our relation to all that lives, as such, that it must flow in future, as from a spring which can never dry up and never become a swamp. That spring is reverence for life.

Law and ethics spring up together from the same idea. Law is so much of the principle of respect for life as can be embodied in an external code; ethics are what cannot be so embodied. The foundation of law is humanity. It is [pg xviii] folly to wish to put out of action the links between law and world-view.

In this way a world-view is the germ of all ideas and dispositions which are determinative for the conduct of individuals and of society.

Flying machines carry men to-day through the air over a world in which hunger and brigandage have a place. It is not in China only that one recognizes the grotesque character of such progress: it is almost typical for mankind generally, and such grotesque progress cannot be changed to the normal till a general disposition prevails which is capable of bringing order again into the chaos of human life through ethics. In the last resort the practical can be realized only through the ethical

What a remarkable circle! Rational thought which thinks itself out arrives at something non-rational and subjective which is a necessity of thought, viz. the ethical affirmation of world and life. On the other hand, what for the purpose of moulding the conditions of existence for individual men and mankind as a whole is rational, that is to say, what is objectively practical in this regard, can only be brought about by individuals perseveringly putting into action the above-mentioned non-rational and subjective. The non-rational principle underlying our activity, a principle which is provided for us by rational thought, is the sole rational and practical principle underlying all the happenings which are to be produced through human action. Thus the rational and the

non-rational, the objective and the subjective proceed each from the other, and return each into the other again. Only when the play of this mutual interchange is in full activity do normal conditions of existence arise for men and mankind. Let it be disturbed and the abnormal develops.

I have, then, in this book written the tragedy of the search for a world-view, and have myself trodden a new path to the same goal. Whereas Western thought has not arrived at any goal because it would not venture resolutely into the desert of scepticism about knowledge of the world, [pg xix] I make my way through this desert with calm confidence. It is, after all, only a narrow strip, and it lies in front of the ever-green oasis of an elemental world-view which grows out of thought about the will-to-live. In my attempt, however, to reach a world-view by this new method, I am conscious of having done no more than put together and think out to conclusions many gropings after this new method which were made by other seekers during the period covered.

But I also put into this book my conviction that mankind must renew itself in a new temper of mind, if it is not to be ruined. I entrust to it, further, my belief that this revolution will come about, if only we can make up our minds to become thinking men.

A new Renaissance must come, and a much greater one than that in which we stepped out of the Middle Ages; a great Renaissance in which mankind discovers that the ethical is the highest truth and the highest practicality, and experiences at the same time its liberation from that miserable obsession by what it calls reality, in which it has hitherto dragged itself along.

I would be a humble pioneer of this Renaissance, and throw the belief in a new humanity, like a torch, into our dark age. I make bold to do this because I believe I have given to the disposition to humanity, which hitherto has ranked only as a noble feeling, a firm foundation in a world-view which is a product of elementary thinking and can be made intelligible to everyone. Moreover, it has gained thereby a power of attracting and convincing which it has not had hitherto; and is capable now of coming to terms in energetic and consistent fashion with our so-called reality, and of proving its full value within it.

ALBERT SCHWEITZER.

July, 1923.

The two instalments of my Philosophy of Civilization which are now ready—_The Decay and Restoration of [pg xx] Civilization_ and _Civilization and Ethics_—will be followed by two others. In the next, which will be entitled _The World-view of Reverence for Life_, I elaborate this world-view, which so far I have only sketched for a conclusion to my discussion of the search for a world-view, as carried on down to the present day. The fourth and last will treat of the Civilized State.

FOOTNOTES INDEX [287]

CIVILIZATION AND ETHICS

CHAPTER I

THE CRISIS IN CIVILIZATION AND ITS SPIRITUAL CAUSE

The material and spiritual elements in civilization

OUR civilization is going through a severe crisis.

Most people think that the crisis was produced by the war, but that is wrong. The war, with everything connected with it, is only a phenomenon of the condition of un-civilization in which we find ourselves. Even in States which took no part in the war, and on which the war had no direct influence, civilization is shaken, only the fact is not so clearly evident in them as in those which were hard hit by the consequences of its peculiarly cruel spiritual and material happenings.

Yet is there any real, live thought going on among us about this collapse of civilization, and about possible ways of working ourselves up out of it? Scarcely! Clever men stumble about in seven-league boots in the history of civilization and try to make us understand that civilization is some kind of natural growth which blossoms out in definite peoples at definite times and then of necessity withers, so that new peoples with new civilizations must keep replacing the worn-out ones. When they are called upon, indeed, to complete their theory by telling us what peoples are destined to be our heirs, they are somewhat embarrassed. There are, in fact, no peoples to be seen whom one could imagine to be capable of even a portion of such a task. All the peoples of the earth have been in large measure under the influence both of our civilization [pg 002] and of our lack of it, so that they share more or less our fate. Among none of them are to be found thoughts which can lead to any considerable original movement of civilization.

Let us put on one side cleverness and interesting surveys of the history of civilization, and busy ourselves in a practical way with the problem of our endangered civilization. Of what character is this degeneration in our civilization, and why has it come about?

To begin with, there is one elementary fact which is quite obvious. The disastrous feature of our civilization is that it is far more developed materially than spiritually. Its balance is disturbed. Through the discoveries which now place the forces of Nature at our disposal in such an unprecedented way, the relations to each other of individuals, of social groups, and of States have undergone a revolutionary change. Our knowledge and our power have been enriched and increased to an extent that no one would have thought possible. We have thereby been enabled to make the conditions of human existence incomparably more favourable in numerous respects, but in our enthusiasm over our progress in knowledge and power, we have come to a defective conception of what civilization is. We value too highly its material achievements and no longer keep in mind as vividly as is desirable the importance of the spiritual. Now the results are upon us, and summon us to reflect. They tell us in terribly harsh language that a civilization which develops only on its material side but not in corresponding measure on its spiritual side, is like a ship which with defective steering gear gets at a constantly accelerating pace out of control, and thereby heads for a catastrophe.

The essential nature of civilization does not lie in its material achievements, but in the fact that individuals keep in mind the ideals of the perfecting of man, and the improvement of the social and political conditions of peoples, and of mankind as a whole, and that their habit [pg 003] of thought is determined in living and constant fashion by such ideals. Only when individuals work in this way as spiritual forces on themselves and on society is the possibility given of solving the problems which have been produced by the facts of life, and of attaining to a general progress which is valuable in every respect. Whether there is rather more or rather less of material achievement to record is not what is decisive for civilization. Its fate depends on whether or no thought keeps control over facts. The issue of a voyage does not depend on whether the vessel's pace is somewhat quicker or somewhat slower, but on whether it steers a correct course, and its steering gear keeps in good condition.

Revolutions in the relations of life between individuals, society, and peoples, as they follow in the train of our great material achievements, make, if they are to show real progress in the sense of valuable civilization, higher demands on the habit of thought of civilized people, just as the increased speed of a ship presupposes greater reliability in rudder and steering gear. Advances in knowledge and power work out their effects on us almost as if they were natural occurrences. It is not within our power so to direct them that they influence favourably in every respect the relations in which we live, but they produce for individuals, for society, and for nations, difficult and still more difficult problems, and bring with them dangers which it is quite impossible to estimate beforehand. Paradoxical as it may seem, our advances in knowledge and power make true civilization not easier but more difficult. One can even say that, judging by the events of our own and the two preceding generations, we are almost entitled to doubt whether in view of the way in which these material achievements have been showered upon us, true civilization is still possible.

The most widespread danger which material achievements bring with them for civilization consists in the fact that through the revolutions in the conditions of life men [pg 004] become in greater numbers unfree, instead of free. The type of man who once cultivated his own bit of land becomes a worker who tends a machine in a factory; manual workers and independent trades-people become employees. They lose the elementary freedom of the man who lives in his own house and finds himself in immediate connexion with Mother Earth. Further, they no longer have the extensive and unbroken consciousness of responsibility of those who live by their own independent labour. The conditions of their existence are therefore unnatural. They no longer carry on the struggle for existence in comparatively normal relations in which each one can by his own ability make good his position whether against Nature or against the competition of his fellows, but they see themselves compelled to combine together and create a force which can extort for itself better living conditions. They acquire thereby the mentality of unfree men, in which ideals of civilization can no longer be contemplated in the needful purity, but become distorted to correspond with the surrounding atmosphere of struggle.

To a certain extent we have all of us, under modern conditions, become unfree men. In every rank of life we have from decade to decade, if not from year to year, to carry on a harder struggle for existence. Overwork, physical or mental or both, is our lot. We can no longer find time to collect and order our thoughts. Our spiritual dependence increases at the same pace as our material dependence. In every direction we come to conditions of dependence which in former times were never known in such universality and such strength. Economic, social, and political organizations, which are steadily becoming more and more complete, are getting us more and more into their power. The State with its more and more rigid organization holds us under a control which is growing more and more decided and inclusive. In every respect, therefore, our individual being is depreciated. It is becoming more and more difficult to be a personality.

[pg 005]

Thus it is that the progress of our external civilization brings with it the result that individuals, in spite of all the advantages they get, are in many respects injured both materially and spiritually in their capacity for civilization through those very advantages.

It is our progress in material civilization, too, which intensifies in so disastrous a way our social and political problems. Through the social ones we are involved in a class struggle which shakes and throws into confusion economic and national relations. If we go down to rock-bottom, it was machinery and world commerce which brought about the world war, and the inventions which put into our hands such mighty power of destruction made the war of such a devastating character that conquered and conquerors alike are ruined for a period of which no one can see the end. It was also our technical achievements which put us in a position to kill at such a distance, and to wipe out the enemy in such masses, that we sank so low as to push aside any last impulse to humanity, and were mere blind wills which made use of perfected lethal weapons of such destructive capacity that we were unable to maintain the distinction between combatants and non-combatants.

Material achievements, then, are not civilisation, but become civilization only so far as the mental habit of civilized peoples is capable of allowing them to work towards the perfecting of the individual and the community. Fooled, however, by our advances in knowledge and power, we did not reflect on the danger to which we were exposing ourselves by the diminished value we put on the spiritual elements in civilization, and we surrendered completely to a naïve satisfaction at our magnificent material achievements, and went astray into an incredibly superficial conception of civilization. We believed in a progress which was a matter of course, because contained in the facts themselves. Instead of harbouring in our thought ideals approved by reason, and undertaking to mould reality into accordance with them, we were fooled [pg 006] by a vain feeling for reality, and wanted to come through with lowered ideals which were borrowed from it. By taking this course we lost all control over the facts.

Accordingly, just when the spiritual element in culture was necessary in extraordinary strength, we let it waste away.

Civilization and World-View

How could it come about that the spiritual element in civilization became so lost to us?

To understand that, we must go back to the time when it was at work among us in a direct and living way, and the path thereto leads us back into the eighteenth century. Among the Rationalists who approach everything through reason, and would regulate everything in life by rational considerations, we find expression given in elemental strength to the conviction that the essential element in civilization is a habit of thought. It is true that they are already impressed by modern achievements in discovery and invention, and do allow to the material side of civilization a corresponding importance. But they nevertheless regard it as self-evident that the essential and valuable element in civilization is the spiritual. That interest is focused first of all on the spiritual progress of men and humanity, and in that they believe with a mighty optimism.

The greatness of these men of the period of the “Aufklärung” lies in this, that they set up as ideals the perfecting of the individual, of society, and of mankind, and devote themselves to these ideals with enthusiasm. The force on which they count for the realizing of them is the general habit of thought; they demand of the human spirit that it shall transform men and the relations in which they live, and they trust to it to prove itself stronger than the facts of life.

But whence came the impulse to set up such high ideals of civilization, and their confidence of being able to realise [pg 007] them? It was from their view of the world (Weltanschauung).

The Rationalist world-view is optimistic and ethical, its optimism consisting in this, that it assumes as ruling in the world a general purposive adaptation which is directed to the perfecting of the world, and from this purposiveness the efforts of individual men and of mankind to secure material and spiritual progress derive meaning and importance and a guarantee of success.

This world-view is ethical because it regards the ethical as something in accordance with reason, and on that ground demands from man that, putting egoistic interests behind him, he shall devote himself to all ideals that are waiting for realization, taking the ethical as in everything the standard by which to judge. A habit of humane thought is for the Rationalists an ideal which they can be induced by no consideration to resign.

When at the close of the eighteenth century and the beginning of the nineteenth the reaction against rationalism set in and criticism began to play upon it, its optimism was reproached as being superficial and its ethics as being sentimental. But the good it did, in spite of its manifold imperfections, by inspiring men with ideals of civilization grounded in reason, the spiritual movements which criticise it and take its place cannot develop in the same way. The energy of thought about civilization decreases imperceptibly but

steadily. In proportion as the world-view of rationalism is left behind, the feeling for actuality makes its influence felt, until at last, from the middle of the nineteenth century onwards, ideals are borrowed no longer from reason but from actuality, and we therewith sink still further into a state of uncivilization and lack of humanity. This is the clearest and the most important of all the facts which can be established in the history of our civilization.

What has it to tell us? It tells us that there is a close connexion between civilization and world-view. Civilization is the product of an optimistic-ethical view of the world. [pg 008] Only in proportion as the prevalent world-view is one which is world- and life-affirming and at the same time ethical, do we find ideals of civilization put forward and kept influential in the habits of thought of individuals, and of society.

That this inner relation between civilization and the world-view of civilized peoples has never received the attention that it deserves, is the result of there having been among us so little real meditation on the essential nature of civilization.

What is civilization? It is the sum total of all progress made by men and mankind in every sphere of action and from every point of view, so far as this progress helps towards the spiritual perfecting of individuals as the progress of all progress.

The impulse to strive for progress in all spheres of action and from every point of view comes to men out of an optimistic world-view which affirms the world and life to be something valuable in themselves, and consequently bears within itself a compulsion to raise to its highest possible value all that is, so far as it can be influenced by us. Hence come will and hope, and effort directed to the improvement of the condition of individuals and of society, of peoples and of mankind. This leads to a lordship of the spirit over the powers of Nature, to the completion of the religious, social, economic, and practical grouping of men, and to the spiritual perfecting of individuals and of the community.

Just as the world- and life-affirming, that is, the optimistic world-view is alone capable of stirring men to effort aimed at promoting civilization, so in an ethical world-view alone is there latent the power to make men, when putting aside and giving up altogether their selfish interests, persevere in such effort for civilization, and keep them always turned in the direction of the spiritual and moral perfecting of the individual as the essential object of civilization. Bound the one to the other, then, world- and [pg 009] life-affirming world-view and ethics think out in harmony the ideals of true, complete civilization and set to work at realizing them.

If civilization remains incomplete or its level falls, this rests in the last resort on the fact that either the world- and life-affirmation of the world-view, or its ethics, or both of them have remained undeveloped or have gone backwards. And that is the case with us. It is evident that the ethics required for civilization have gone out of use.

For decades we have been accustoming ourselves increasingly to measure with relative ethical standards, and no longer to allow ethics to have their say in all questions alike. This renunciation of consistent ethical judgment we feel as an advance in practicality.

But our world- and life-affirmation also have become shaky. The modern man no longer feels under any compulsion to think about ideals of progress and to will them. To a large extent he has come to terms with actuality. He is much more resigned than he admits to himself, and in one respect he is even outspokenly pessimistic. He does not really believe any more in the spiritual and ethical progress of men and of mankind, which is nevertheless the essential element in civilization.

This stunting of our world- and life-affirmation and of our ethics has its cause in the constitution of our world-view. In regard to this we have since the middle of the nineteenth century been going through a crisis. It is no longer possible for us to arrive at a conception of the universe in which the meaning of the existence of men and of mankind can be recognized, and in which, therefore, there are also contained the ideals which flow from thoughtful world- and life-affirmation and from ethical volition. We are falling more and more into a condition of having no world-view at all, and from our lack of that comes our lack of civilization.

The great question for us is, therefore, whether we have to renounce permanently the world-view which carries within it in all their strength the ideals of the perfecting of men and of mankind, and of ethical effort. If we succeed [pg 010] in establishing again a world-view in which world- and life-affirmation is given in convincing fashion, we shall become masters of the decay of civilization which is in progress, and shall reach again a true and living civilization. Otherwise we are condemned to see the wreck of all attempts to arrest the degeneration. Only when the truth that renewal of civilization can only come by a renewal of our world-view becomes a universal conviction, and a new longing for a world-view sets in, shall we find ourselves on the right path. But this is not yet in prospect. The modern man is still without any correct feeling of the full significance of the fact that he is living with an unsatisfactory world-view, or without any at all. The unnatural and dangerous character of this condition must first be brought home to his consciousness, just as those persons who exhibit disturbances of the stability of their nervous system have to be clearly told

that their vitality is threatened, although they feel no pain. Similarly, we have to stir up the men of to-day to elementary meditation upon what man is in the world, and what he wants to make of his life. Only when they are impressed once more with the necessity of giving meaning and value to their existence, and thus come once more to hunger and thirst for a satisfying world-view, are the preliminaries given for a spiritual condition in which we become again capable of civilization.

But in order to learn the way to such a world-view we must see clearly why the struggle undertaken by the European spirit to secure it was for a time successful, but during the second half of the nineteenth century came to an unfortunate end.

Because our thinking is too little occupied with civilization it has been insufficiently noticed that the most important part of the history of philosophy is the history of man's struggle for a satisfactory world-view. Regarded in this light, the history unrolls itself like a tragic drama.

[pg 011]

CHAPTER II

THE PROBLEM OF THE OPTIMISTIC WORLD-VIEW

The Western and the Indian conceptions of civilization

FOR us Westerners civilization consists in this, that we work for the perfecting of ourselves and of the world at the same time.

But do the activities that are directed outwards and inwards necessarily belong together? Cannot the spiritual and moral perfecting of the individual, which is the ultimate aim of civilization, also be secured if he works for himself only and leaves the world and its circumstances to themselves? Who gives us any guarantee that the course of the world can be influenced so as to promote the special aim of civilization, viz., the perfecting of the individual? Who tells us that it has any meaning at all which can be further developed? Is not any action of mine which is directed on the world a diversion of what could be directed on myself, though everything depends finally upon the latter?

Moved by these doubts the pessimism of the Hindus and that of Schopenhauer refuse to allow any importance to the material and social achievements, which form the outward and visible part of civilization. About society, nation, mankind, the individual is not to trouble himself; he is only to strive to experience in himself the sovereignty of spirit over matter.

This, too, is civilization, in that it pursues the final object of the latter, viz., the spiritual and ethical perfecting of the individual. If we Westerners pronounce it incomplete, we must not do so too confidently. Do the outward progress of mankind and the inner completion of the individual really belong together as we imagine them to? Are we not, under an illusion, forcing together things which are [pg 012] different in kind? Has the spirit in one kind of action actually some gain for the other?

What we set up as our ideal we have not realized. We lost ourselves in outward progress, allowing the moralization and inward deepening of the individual to come to a stop. So we have not been able to produce practical proof of the correctness of our view of what civilization is. We cannot, therefore, simply put aside that other narrower conception, but must come to terms with it.

There will come a time—it is already being prepared for—when pessimistic and optimistic thought, which have hitherto talked past each other almost as strangers, will have to meet for practical discussion. World-philosophy is just dawning. It will shape itself in a struggle as to whether its world-view shall be optimistic or pessimistic.

The struggle for the optimistic world-view

The history of Western philosophy is the history of the struggle for an optimistic world-view. If in antiquity and in modern times the peoples of Europe have managed to produce a civilization, it is because in their thought the optimistic world-view was dominant, and held the pessimistic permanently in subjection, although it was not able to suppress it altogether.

The accessions of knowledge which have come in the course of our philosophy have been nothing in themselves: they always stand in the service of one world-view or the other, and attain only in it to their real significance.

But the characteristic thing about the way in which the settlement is made on each occasion, is that it never is made openly. The two world-views are never brought face to face and the case of each heard. That the optimistic alone is in the right is a conviction which is accepted as more or less self-evident. The only thing felt as a problem is how to marshal all possible knowledge in the

triumphal procession of proof to defeat the other, and to knock on the head anything that may still wish to rise in its defence.

[pg 013]

Since the pessimistic world-view has never made its presence properly felt, Western thought manifests a lofty unwillingness to understand it, though it has a splendid faculty for detecting it. Where it finds, as in Spinoza, too little interest for activity directed upon the world, it reacts immediately with rejection of it. Yet all objectively thinking investigation of the reality of nature is disliked by it because it may lead to the central position of the human spirit in the world being insufficiently emphasised. It is because materialism seems likely to be the last ally of pessimism that it carries on so embittered a struggle against it.

In the discussion of the problem of the theory of knowledge from Descartes to Kant and beyond him it is really the cause of the optimistic world-view which is being maintained. That is why the theoretical possibility of a depreciation or a denial of the world of sense is attacked with such obstinacy. By proving the ideality of space and time Kant hopes to make finally secure the optimistic world-view of rationalism with all its ideals and demands. Only so can it be explained that the most acute examinations of the theory of knowledge are carried through with the most naïve conclusions about world-view. The great post-Kantian systems of thought, however much they differ from one another in their subject-matter and the process of the speculation with which they deal with it, are all united in this, that they crown the optimistic world-view in their cloud-castles as the ruler of the universe.

To fit in the aims of mankind with those of the universe in a logically convincing fashion, that is the endeavour in which European philosophy serves the optimistic world-view. Anyone who does not help, or who is indifferent about it, is an enemy.

In its prejudice against scientific materialism philosophy was right. Materialism has done much more to shake the position of the optimistic world-view than Schopenhauer has, although it never proceeded against it with outspoken hostility. When, after the collapse of the great systems, [pg 014] it was allowed to seat itself at table with philosophy, which had now become more modest, it even exerted itself to find out in what sort of tone the latter would like the conversation to be carried on. In dealing with Darwin and others, philosophizing natural science made touchingly naïve attempts so to extend and stretch out the history of zoological development which led up to man, that mankind and with it the spiritual should appear again as the goal of the world-process, as in the speculative systems. But in spite of these well-meant efforts of the proletarian guest the conversation could no longer be carried on in the old spirit. Of what use was it for him to try to be better than his reputation? He brought with him more respect for nature and facts than was consistent with the convincing establishment of the optimistic world-view. He therefore shook it, even when he did not intend to.

To such a disregard of nature and science as was shown by the earlier philosophy we can never return. Nor can we expect the return of a system of thought which makes it possible to discover in any convincing way in the universe the aims and objects of mankind, as was allowed by the old methods. The optimistic world-view ceases, therefore, to be self-evident to us, or to be demonstrable by the arts of philosophy. It must give up the idea of finding for itself a solid foundation.

Optimism and Pessimism

Confusion is caused by the fact that the optimistic and pessimistic world-views seldom come forward in their purity in the history of human thought. Their relations are usually such that the one is predominant, while the other treats with it without being officially recognized. In India a tolerated world- and life-affirmation maintains for pessimism something of interest in the external civilization which it nominally denies. With us pessimism slips in and gnaws at the civilizing energies of the optimistic view, the result being that belief in the spiritual progress of [pg 015] mankind has left us. From it, too, comes the fact that we everywhere conduct the business of life with lowered ideals.

Pessimism is a lowered will-to-live, and is to be found wherever man and society are no longer under the pressure of all those ideals of progress which must be thought out by a will-to-live that is consistent with itself, but have sunk to the level of letting actuality be, over wide stretches of life, nothing but actuality.

It is where pessimism is at work in this anonymous fashion, that it is most dangerous to civilization. It attacks then the most valuable ideas belonging to life-affirmation, leaving the less valuable ones untouched. Like some concealed source of magnetic power it disturbs the world-view's compass, so that it takes, without suspecting it, a wrong course. Thus the unavowed mixture of optimism and pessimism in our thought has the result that we continue to approve the external blessings given us by civilization, things which to thinking pessimism are a matter of indifference, while we abandon that which alone it holds to be valuable, the pursuit of inner perfection. The desire for progress which is directed to objects of sense, goes on functioning because it is nourished by actuality,

while that which reaches after the spiritual becomes exhausted, because it is thrown back upon the inner stimulus which comes from the thinking will-to-live. As the tide ebbs, objects which reach deep down are left stranded, while what is just on the surface remains afloat.

Our degeneration, then, traced back to our world-view and what resulted from it, consists in true optimism having, without our noticing it, disappeared from among us. We are by no means a race weakened and decadent through excessive enjoyment of life, and needing to pull ourselves together to show vigour and idealism amid the thunderstorms of history. Although we have retained our vigour in most departments of the direct activities of life, we are spiritually stunted. Our conception of life with all that depends on it has been lowered both for individuals and for the community. The higher forces of volition and [pg 016] influence are impotent in us, because the optimism from which they ought to draw their strength has become imperceptibly permeated with pessimism.

A characteristic feature of the presence at the same time of optimism and pessimism as lodgers in “Thoughtless House” is that each goes about in the other’s clothes, so that what is really pessimism gives itself out among us as being optimism, and _vice versâ_. What passes for optimism with the mass of people is the natural or acquired faculty of seeing things in the best possible light. This illumination of them is the result of a lowered conception of what ought to be now and in the future. A person ill with consumption is brought by the poison of the disease into the condition which is called Euphoria, so that he experiences an imaginary feeling of health and strength. Similarly there is an external optimism present in individuals and in society just in proportion as they are, without realizing it, infected with pessimism.

True optimism has nothing to do with any sort of lenient judgement. It consists in contemplating and willing the ideal in the light of a deep and self-consistent affirmation of life and the world. Because the spirit which is so directed proceeds with clear vision and impartial judgement in the valuing of all that is given, it wears to ordinary people the appearance of pessimism. That it wishes to pull down the old temples in order to build them again more magnificently is by the vulgar optimism put down to its discredit as sacrilege.

The reason, then, why the only legitimate optimism, that of volition inspired by imagination, has to carry on such a hard struggle with pessimism is that it always has first to track the latter down in vulgar optimism and unmask it. That is a task which optimism has never finished, for so long as it allows the enemy to emerge in any shape there is danger for civilization. When that happens, activity in promoting the special aims of civilization always diminishes, even if satisfaction with its material achievements remains as strong as before.

[pg 017]

Optimism and pessimism, therefore, do not consist in counting with more or less confidence on such or such a future for the existing state of things, but in what the will desires to have as the future. They are qualities not of the judgement, but of the will. The fact that up to now that inadmissible definition of these qualities was current side by side with the correct one, so that there were four items to deal with instead of two, made the game easier for the unthinking by deceiving us about what true optimism is. Pessimism of the will they passed off as optimism of the judgement, and optimism of the will they put aside as pessimism of the judgement. These false cards must be taken from them, so that they may not continue to deceive the world in such a fashion.

Optimism, Pessimism, and Ethics

In what relation do optimism and pessimism stand to ethics?

That close and peculiar relations do exist between them is clear from the fact that in the thought of mankind the two struggles, that for optimistic or pessimistic world-view and that about ethics, are usually involved in each other. It is the general belief that when one is being fought out the other is being fought as well.

This mutual connexion is very convenient for thought. When a foundation for ethics is being laid, optimistic or pessimistic arguments are unawares pressed into the service, and _vice versâ_ ethical arguments when optimism or pessimism have to be established. In this process Western thought lays most stress on justifying a life-affirming ethical system, that is an activist one, and thinks that merely by doing so it has proved the case for optimism in its world-view. With Indian thought the most important thing is finding a logical foundation for pessimism, and the justifying of a life-denying ethical system, _i.e._ a passivist one, is rather a derivative from that.

The confusion which resulted from the two struggles for [pg 018] optimism and pessimism and for ethics not being kept distinct, has contributed almost more than anything else to prevent the thought of mankind from attaining to clarity.

It was an easy mistake to make. The question whether it is to be affirmation or denial of life and the world, crops up in ethics in the same way as in the dispute between optimism and pessimism. Things which by their nature belong together feel themselves drawn together, so that optimism naturally thinks it can support itself on an affirmative ethical system, and pessimism thinks the same about a negative one. Nevertheless, the result has hitherto always been that neither of these two closely-related entities could stand firm, because neither of them chose to depend on itself alone.

[pg 019]

CHAPTER III

THE ETHICAL PROBLEM

The difficulties of ethical perception

HOW came mankind to think about morality and to make progress in that sphere of thought?

It is a picture of confusion that unrolls itself before the eyes of anyone who undertakes a journey through the history of man's search for the ethical. The progress made in that sphere of thought is inexplicably slow and uncertain. That the scientific view of the world could be delayed in its rise and development is to a certain extent intelligible, for its advance depended more or less on the chance of there existing gifted observers, whose discoveries in the realm of the exact sciences and the knowledge of nature was needed first, to provide new horizons and to point out new paths for thought.

But in ethics thought is thrown back entirely on itself: it has to do only with man himself and his self-development, which goes on by a process of causation from within. Why, then, does it not make better progress? Just because man himself is the material which has to be investigated and moulded.

Ethics and æsthetics are the step-children of philosophy. They both deal with a subject which is coy about submitting itself to reflexion, for they both treat of spheres in which man exercises his purely creative activities. In science man observes and describes the course of nature, and tries to penetrate its mysteries. In practical matters he uses and moulds it by applying what he has grasped of it outside his own person. But in his moral and artistic activities he uses knowledge and obeys impulses, [pg 020] perceptions, and laws which originate in himself. To establish these firmly and to create ideals from them is an undertaking which can be successful to a certain extent only. Thought lags behind the material on which it exercises itself.

This is evident from the fact that the examples with which ethics and æsthetics try to work upon reality are usually not quite consistent and are often foolish. And how far from simple is whatever is laid down in either this or that! How the assertions made contradict each other! The guidance that an artist can get for his activities from the best works on æsthetics is but small. Similarly, a business man who seeks in a work on ethics advice as to how, in any given case, he is to bring the demands of his business into harmony with those of ethics, can seldom find any satisfactory information.

The inadequacy in this respect of æsthetics is not of great importance for the spiritual life of mankind. Artistic activity is always the peculiar affair of individuals whose natural gifts develop more by the actual production of works of art than by consideration of the conclusions arrived at by æsthetic theorizing.

With ethics, however, it is a matter of the creative activity of the mass of men, an activity which is largely determined by the principles which are current in the general thought of the time. The absence of that progress which is still possible in ethics is something tragic.

Ethics and æsthetics are not sciences. Science, as the description of objective facts, the establishment of their connexion with one another, and the drawing of inferences from them, is only possible when there is a succession of similar facts to be dealt with, or a single fact in a succession of phenomena, when, that is, there is a subject matter which can be reduced to order under a recognized law. But there is no science of human willing and doing, and there never can be. Here there are only subjective and infinitely various facts to be studied, and their mutual connexion lies within the mysterious human ego.

It is only the history of ethics that is scientific, and that [pg 021] only so far as a history of man's spiritual life is scientifically possible.

The importance of thought about ethics

There is, therefore, no such thing as a scientific system of ethics; there can only be a thinking one. Philosophy must give up the illusion which it has cherished even down to the present day. As to what is good and what is bad, and about the considerations in which we find strength to do the one and avoid the other, no one can speak to his neighbour as an expert. All that one can do is to impart to him so much as one finds in oneself of that which ought to influence everybody, though better thought out perhaps, and stronger and clearer, so that noise has become a musical note.

Is there, however, any sense in ploughing for the thousand and second time a field which has already been ploughed a thousand and one times? Has not everything which can be said about ethics already been said by Lao-tse, Confucius, the Buddha, and Zarathustra; by Amos and Isaiah; by Socrates, Plato, and Aristotle; by Epicurus and the Stoics; by Jesus and Paul; by the thinkers of the Renaissance, of the “Aufklärung,” and of Rationalism; by Locke, Shaftesbury, and Hume; by Spinoza and Kant; by Fichte and Hegel; by Schopenhauer, Nietzsche, and others? Is there a possibility of getting beyond all these so materially contradictory convictions of the past to something new which will have a stronger and more lasting influence? Can the ethical kernel of the thoughts of all these men be collected into an idea of the ethical, which will unite all the energies to which they appeal? We must hope so, if we are not to despair of the fate of the human race.

Does thought about ethics bring more ethics into the world? The confused picture offered us by the history of ethics is enough to make one sceptical about it. On the other hand, it is clear that ethical thinkers like Socrates, Kant, or Fichte had a moralizing influence on many of their [pg 022] contemporaries. From every revival of ethical reflexion there went forth ethical movements which made the contemporary generation fitter for its tasks. If any age lacks the minds which force it to reflect about the ethical, the level of its morality sinks and with it its capacity for answering the questions which present themselves to it.

In the history of ethical thought we wander in the innermost circles of world-history. Of all the forces which mould reality morality is the first and foremost. It is the determining knowledge which we must wring from thought. Everything else is more or less secondary.

For this reason everyone who believes that he can contribute something to help forward the ethical self-consciousness of society and of individuals has the right to speak now, although it is political and economic questions that the present day prescribes for study. For what is inopportune is really opportune. We can accomplish something lasting in the problems of political and economic life only if we approach them as men who are trying to think ethically. All those who help forward in any way our thought about ethics are working for the coming of peace and prosperity to the world. They are engaged in the higher politics, and the higher rational economics, and even if all they can do is nothing more than to bring ethical thinking to the fore, they have nevertheless done something valuable. All reflexion about ethics has as one result a raising and rousing of the general disposition to morality.

The search for a basic principle of morality

But however certain it is that every age lives by the energies which have sprung from its thought about ethics, it is equally certain that up to now the ethical thoughts which have become current have after a longer or a shorter period lost their power of convincing. Why has the establishment of an ethical system never met with more than a partial and temporary success, and never been a permanency? Why is the history of the ethical thinking of [pg 023] mankind the history of inexplicable stoppages and fallings-back? Why has there been in this sphere no organic progress which allows one period to build upon the achievements of preceding ones? Why in the sphere of ethics do we live in a town full of ruins, in which one generation builds for itself here, and another there, what is absolutely necessary?

“To preach morality is easy, to establish it is hard,” says Schopenhauer, and that saying shows what the problem is.

In every effort of thought about ethics there is to be seen, distinctly or indistinctly, the search for a basic principle of morality, which needs no support outside itself, and unites in itself the sum total of all moral demands. But no one has ever succeeded in really formulating this principle. Elements only of it were brought to light and given out to be the whole, until the difficulties which emerged destroyed the illusion. The tree, however finely it sprouted, did not live to grow old, because it was unable to send its roots down into the permanently nourishing and moisture-giving earth.

The chaos of ethical views becomes to some extent intelligible as soon as one sees that we are concerned with differing and mutually contradictory views about fragments of the basic principle. The contradiction has its foundation in their incompleteness. There is ethical matter in what Kant objects to in the ethics of rationalism, as also in what he puts in its place; in that part of Kant’s

writings where his conception of the moral is opposed by Schopenhauer, as also in what is to take its place in the ethical system of the latter. Schopenhauer is ethical in the points on which Nietzsche attacks him, and Nietzsche is ethical in his opposition to Schopenhauer. What is wanted is to find the fundamental chord in which the dissonances of these varied and contradictory ethical ideas unite in producing harmony.

The ethical problem, then, is the problem of a basic principle of morality, which is founded in thought. What is the common element of good in the manifold goods which we feel to be such? Is there such a universally valid [pg 024] conception of the good? If there is, in what does it consist, and how far is it real and necessary for me? What influence has it over my general disposition and my actions? Into what relations with the world does it bring me?

It is, then, on the basic principle of the moral that the attention of thought has to be fixed. The mere giving of a list of virtues and duties is like striking notes at random on the piano and thinking it is music. And when we come to discuss the works of earlier moralists, it is only the elements in them which can help the establishment of an ethical system that will interest us, not the way in which any system has been advocated.

Otherwise there is no success for any attempt to bring order into chaos. How utterly at sea Friedrich Jodl_(_2_)_ is in his history of ethics, the most important existing work in this department, when he tries to estimate the relative values of the various ethical standpoints! Failing to judge them directly by their distance from an initial basic principle of morality, he is unable to establish a standard of comparison. He gives us, therefore, only a survey of ethical views, and no history of the ethical problem.

Religious and philosophical ethics

When we come to look for the fundamental principle of morality, are we concerned only with the direct attempts of philosophy to find it? No, we are concerned with every kind, those of religion as well as others. We must trace out the whole experience of mankind in its search for the ethical.

The raising of a dividing wall between philosophical ethics and religious ethics is based on the mistaken idea that the former are scientific and the latter non-scientific. But neither of them is either: they are both alike merely thought; only one has freed itself from acceptance of the traditional religious world-view, while the other still maintains its connexion with it.

[pg 025]

The difference, however, is merely relative. Religious ethics appeal, indeed, to a supernatural authority, but that is rather the form which they assume. As a matter of fact, however high they rise, they still seek to find an independent basic principle of morality. In every religious genius there lives an ethical thinker, and every really deep philosophical moralist is in some way or other religious.

How indeterminate is the border-line is shown by Indian ethics. Are they religious, or are they philosophical? Originating in the thought of the priests, they claim to be a deeper exposition of the demands of religion, but in essential nature they are philosophical. With the Buddha and others, they venture to make the step from pantheism to atheism, but without giving up their claim to be religious. Spinoza and Kant, however, who are counted among philosophical moralists, do, if we judge by the general direction of their thought, belong at the same time to the religious ones.

It all depends on a relative difference in methods of thought. The one group works towards the basic principle of ethics by a more intuitive process, the other by a process which is more analytical. It is the depth, not the method of the thought, which decides the matter. The more intuitive thinker produces his ethical thought like an artist who with the production of an important work of art opens up new horizons. In deep-reaching moral sayings like the beatitudes of Jesus the basic principle of morality shines out. There comes progress in the recognition of what is moral, even if the provision of a foundation for it fails to advance in the same way.

On the other hand, the searching for the basic principle of the moral by the process of critical analysis may lead to an impoverished system of ethics, because there runs through it the effort to take into account only what is connected with the idea that seems to be what is being sought for. That is why philosophical ethics are as a rule so far behind practical ethics, and have so little direct influence. While religious moralists in one mighty word can get down to the [pg 026] waters flowing far below the surface, philosophical ethics often dig out nothing but a slight hollow in which a puddle forms.

Nevertheless, it is rational thinking alone which is able to pursue the search for the basic principle with perseverance and hope of success. It must find it at last, if it only goes deep enough, and is simple enough.

The weakness of all ethics hitherto, whether philosophical or religious, has lain in this, that they have not shown individuals how to deal directly and naturally with reality. To a large extent they merely talk “about it and about.” They do not touch a man’s daily experience, and therefore they exert no permanent pressure upon him. The result is lack of ethical thought, and mere platitudes about ethics.

The true basic principle of the ethical must be not only something universally valid, but something absolutely elementary and inward, which, once it has dawned upon a man, never lets him loose, which as a matter of course runs like a thread through all his meditation, which never lets itself be thrust aside, and which continually challenges him to come to an understanding with reality.

For centuries men who navigated the seas guided themselves by the stars. In time they rose above this imperfect method through the discovery of the magnetic needle, which by its natural principle of activity pointed them to the north. Now they can tell where they are in the darkest night on the most distant sea. That is the kind of progress that we have to seek in ethics. So long as we have nothing but an ethical system of ethical sayings, we direct our course by stars, which, however brilliant their shining, give us only more or less reliable guidance, and can be hidden from us by rising mist. During a stormy night they leave mankind, as we know by recent experiences, in the lurch. If, however, we have in our possession a system of ethics as a principle which is a necessity of thought and comes to clearness within ourselves, there begins a far-reaching ethical deepening of individuals, and steady ethical progress in mankind.

[pg 027]

CHAPTER IV

RELIGIOUS AND PHILOSOPHICAL WORLD-VIEWS

The world-views of the world-religions

IN the world-religions we can see powerful attempts to establish an ethical world-view.

The religious thinkers of China, Lao-tse (born 604 B.C.), Kung-tse (Confucius, 537-479 B.C.), Meng-tse (372-289 B.C.) and Chwang-tse (fourth century B.C.), all try to ground the ethical in a world- and life-affirming nature-philosophy. In so doing they arrive at a world-view which, because it is optimistic-ethical, contains incentives to inward and outward civilization.

The religious thinkers of India also, the Brahmanic philosophers, the Buddha (560-480 B.C.), and the Hindus, start, like the Chinese, from thought about the existing world, _i.e._ from nature-philosophy. They do not, however, take a world- and life-affirming view of it, but a world- and life-denying one. Their world-view is pessimistic-ethical, and contains, therefore, incentives to inward civilization only, not to outward as well.

Chinese religiousness, and Indian, recognize only a single world-principle. They are monistic and pantheistic. Their world-view has to solve the problem of how far we can recognize the original source of the world as ethical, and how far, correspondingly, we become ethical by the surrender to it of our will.

In contrast to these monistic-pantheistic world-views we find dualistic ones in the religion of Zarathustra (sixth century B.C.), in that of the Jewish prophets (from the eighth century B.C. onwards), and in those of Jesus and Mohammed, this last, however, showing itself to be in [pg 028] all points unoriginal and decadent. These religious thinkers do not start from an investigation of the existence which manifests itself in the universe, but from a view of the ethical which is quite independent of it. They put it in opposition to natural happenings. Accordingly they assume the existence of two world-principles, the natural and the ethical. The first is in the world, and has to be overcome; the other is incorporated in an ethical personality which is outside the world and has been given the final authority in this sphere.

If among the Chinese and the Hindus the basic principle of morality was life in harmony with the world-will, so among dualists it is an attempt to be something different from the world in harmony with an ethical divine personality which is outside and above the world.

The weakness of dualistic religions is that their world-view, because it rejects every kind of nature-philosophy, is always naïve. Their strength lies in the fact that they have the ethical within themselves, directly present and with undiminished force. They have no need to strain it and explain it, as monists have to, so as to be able to conceive it as an effluence from the world-will which

reveals itself in nature.

The world-views of the dualistic world-religions, taken as a whole, are optimistic. They live in the confident belief that ethical force will prove superior to natural, and so raise the world and mankind to true perfection. Zarathustra and the older Jewish prophets represent this process as a kind of world-reform. The optimistic element in their world-view asserts itself in a quite natural way. They have the will, and the hope of being able to transform human society and to make the races of the world fit for their higher destiny. Progress in any department of life means for them something gained, for they think of inward and outward civilization together.

With Jesus the value of the optimistic element in his world-view is impaired by the fact that he looks forward to the perfected world as a result of a catastrophic end to the natural one, and while with Zarathustra and the older [pg 029] Jewish prophets the Divine intervention is to a certain extent only the completion of the human activities which have been directed to the perfecting of the world, it is with Jesus the only thing which has to be taken into account. The kingdom of God is to appear in a supernatural way; it is in no way prepared for by any effort made by mankind to attain to civilization.

The world-view of Jesus, because it is fundamentally optimistic, accepts the ends aimed at by outward civilization. Being, however, entangled in the expectation of the end of the world, it is indifferent to all attempts made to improve the temporal, natural world by a civilization which organizes itself on lines of outward progress, and it busies itself only with the inward ethical perfecting of individuals.

Just in proportion, however, as the Christian world-view draws the consequences of the world's not coming to an end, and accepts the idea that the kingdom of God must be established by a process of development which transforms the natural world, it begins to understand and be interested in the completing of social organization, and in all such progress in outward civilization as contributes to it. Then the optimistic element in the world-view can again work unhindered side by side with the ethical. Thus we get an explanation of the fact that Christianity, which in the ancient world showed itself hostile to civilization, seeks in modern times with more or less success to conduct itself as the world-view which is for progress in every sphere of activity.

The world-views of the world-religions and that of Western thought

The questions which press for an answer from the world-religions in their struggle to reach an ethical and an optimistic-ethical world-view, are the same as those which present themselves to Western philosophy also. The great problem is to think out a connexion between the universe and ethics.

[pg 030]

The three types of world-view which show themselves in the world-religions, recur also in Western philosophy. The latter, too, attempts to find an ethical code either in a world- and life-affirming, or in a world- and life-denying, nature-philosophy, or it attempts, rejecting more or less completely all nature-philosophy, to reach a world-view which is in itself ethical. Only, it at the same time does its best to avoid acknowledging, and indeed to conceal, the naïve and dualistic element which is inevitably encountered when this last method of procedure is followed.

The world-views, then, of the world-religions, and that of Western philosophy, do not belong to different worlds, but stand in close inward relations to one another. Further, the distinctions between a religious world-view and a philosophical one is a quite superficial one. The religious world-view which seeks to comprehend itself in thought becomes philosophical, as is the case among the Chinese and the Hindus. On the other hand a philosophical world-view which goes really deep, assumes a religious character.

Although Western thought does, in principle, approach the problem of world-view without any presuppositions, it has not been able to keep itself entirely from being influenced by religious world-views. From Christianity it has received impulses of a decisive character, and the attempt to convert the naïve-ethical world-view of Jesus into a philosophical one has cost it more attention and effort than it admits to itself. With Schopenhauer and his successors the pessimistic monism of India finds expression, and it enriches their reflexion upon the nature of the ethical.

Thus the energies of all the great world-views stream into Western thought, and through the co-operation of these varied forms of thought and energy the latter is enabled to exalt into a universal conviction the optimistic-ethical world-view which hovers before its mind, and that too in a strength which it has never displayed in any previous age or in any other part of the world. And that is why Western thought has advanced farthest both in inward civilization and in outward.

[pg 031]

To give a real foundation to the optimistic-ethical world-view Western thought is indeed as little able as any of the world-religions were, and because the West experiences the problem of world-view in its most universal and most pressing form it is the scene of the greatest advances made by the civilized mind, but also of its greatest catastrophes. It experiences portentous changes in its world-view, and is familiar, too, with terrible periods when it has no world-view at all.

It is because our Western thought is so sensitive in both these directions, that it reveals most clearly the questions and difficulties amid which the search for an optimistic world-view moves.

How far does the history of our thought give to us Westerners the explanation of our fate? What road does it indicate to us as the best for our future search after a world-view in which the individual can find inwardness and strength, and mankind progress and peace?

[pg 032]

CHAPTER V

CIVILIZATION AND ETHICS IN THE GRÆCO-ROMAN PHILOSOPHY

The beginnings: Socrates.

IN the seventh century before Christ the Greek spirit begins to free itself from the world-view which underlay the traditional religion, and undertakes the task of establishing another on a foundation of knowledge and thought.

First there comes a nature-philosophy, the result of investigation of Being with reflexion upon what it really is. Then criticism begins its work. Belief in the gods is found unsatisfying, not only because the course of nature is not made intelligible by the rule of dwellers in Olympus, but also because these personalities no longer answer to the demands of feeling which is thoughtful and moral. These two elements, nature-philosophy and criticism, are found united in Xenophanes and Heraclitus in the sixth century B.C.

In the course of the fifth century B.C. Sophists appear, and begin to concern themselves critically with the accepted standards of value current for social life and individual activities._(_3_)_ The result is annihilating. The more moderate of these “Enlighteners” proclaim the overwhelming majority of these standards which pass for moral to be merely claims made by society on its members, leaving open thereby the possibility that a small remainder may be able to prove themselves to rational consideration as moral in [pg 033] themselves. But the younger radical sophists maintain the position that all morality, like all current law, has been invented by organized society in its own interest. Hence the thinking man who is freeing himself from this tutelage will make his own moral standards, and will follow in them nothing but his own pleasure and interests. Thus Western philosophical thought about the problem of ethics and civilisation starts with a shrill dissonance.

What was Socrates (470-399 B.C.) able to contribute, when he came forward to oppose this tendency?

In the place of the simply pleasurable he put the rationally pleasurable.

By rational consideration, he asserts, it is possible to establish a standard of action in which the happiness of the individual, rightly understood, is in harmony with the interests of society. Virtue consists in right knowledge.

That the rationally moral is that which procures for the agent true pleasure, or, what means the same thing, true profit, Socrates draws out into the most diverse applications in the simple everyday discussions which Xenophon has transmitted to us in his _Memorabilia_._(_4_)_ The dialogues of Plato show him going beyond this primitive utilitarianism, and seeking a conception of the good which has been made something inward and aims at the well-being of the soul; which stands, too, in relationship with the beautiful._(_5_)_ How much of these more advanced views are the Master’s own, and how much of his own thoughts his pupil has in this way put into his mouth, cannot now be decided.

That Socrates spoke of an inner, mysterious voice, the “daimonion”, as being the highest moral authority in man is indeed certain, for it is mentioned in his indictment. His [pg 034] utilitarian rationalism is therefore completed by a kind of mysticism. An empirical ethic, that is, one established out of past experience and with a view to future experience, and an intuitive ethic live in him side by

side and undistinguished from one another, to be separated later and developed in contrast to one another in his pupils, the Cynics and Cyrenaics on the one hand, and Plato on the other.

Was Socrates at all conscious that with the bringing back of the moral to that which is rationally pleasurable he builds the road only a short way further, and stops exactly at the point where the real difficulty makes its appearance, viz. that of defining the most general content of the moral as given by reason? Or was he so simple as to regard the general formula he had arrived at as the solution of the difficulty?

The confidence which he displays in all his public life leads us to suppose the latter. In his unaffected simplicity lies his strength. In that perilous hour when Western thought comes to the point of having to philosophize about the moral in order to arrest the dissolution of Greek society which has been begun by a body of unstable and disputatious teachers, the wise man of Athens shatters all scepticism by the mighty earnestness of his conviction that what is moral can be determined by thought. Beyond that general statement he does not go, but he is the source of that serious spirit in which antiquity after his day busied itself with the problem. What would that ancient world have become without him?

Characteristic for this prologue to Western philosophizing about the moral is the indifference with which Socrates stands outside the philosophic efforts to reach a complete world-view. He troubles himself neither about the results of natural science, nor about inquiries into the nature of knowledge, but is busied simply with man in his relation to himself and to society. Lao-tse, Confucius, the Indian philosophers, the Jewish prophets, and Jesus seek to comprehend ethics as somehow or other derived from, or [pg 035] forming part of, a world-view. Socrates gives them no foundation but themselves. On this stage, which has no scenery to form a background, there will appear in succession to him the utilitarians of every age.

And here a remarkable prospect opens to us. To all efforts to determine the content of the moral more help is afforded by the ethic which keeps clear of all connexion with a complete world-view than by any other. Such an ethic is the most practical. And yet this isolation is unnatural. The idea that ethics are rooted in a complete world-view, or must find their completion in one—that is, the idea that one's relations to one's fellow-men and to society are in the last resort rooted in some relation to the world—never loses its natural claim. Hence again and again—already in Plato, then in Epicurus and in the Stoic philosophy—ethics feel the need of again connecting themselves with world-view, and the same process continues in modern thought. But the practical search for the content of the ethical remains the prerogative of those who are busied with ethics in themselves.

In Socrates the ethical mysticism of devotion to the inner voice takes the place of the complete world-view, which was in future to be the foundation of the ethical determination of mankind.

Epicureanism and Stoicism. The Ethic of Resignation

Three tasks were left by Socrates to his successors: to determine more exactly the content of the rationally useful; to give the world the most universal general-notion of the good; and to think ethics into a complete world-view.

What conclusions are come to by those who concern themselves with the first question, and seek to determine the rationally useful from a corresponding experience of pleasure?

As soon as the notion of pleasure is brought into connexion with ethics it shows disturbances, as the magnetic [pg 036] needle does in the neighbourhood of the poles. Immediate pleasure shows itself as incapable in every respect of being reconciled with the demands of ethics, and it is therefore given up. Lasting pleasure is called on to take its place, but this retreat does not suffice. Lasting pleasure, interpreted seriously, can be nothing but pleasure of the mind. Even this position, however, is not tenable. Reflexion upon the ethic which is to produce happiness sees itself compelled at last to give up the positive notion of pleasure in any form. It has to reconcile itself to the negative notion which conceives pleasure as somehow or other a liberation from the need of pleasure. Thus the individualistic, utilitarian ethic, also called Eudæmonism, destroys itself as soon as it ventures to be consistent. This is the paradox which reveals itself in the ethics of antiquity.

Instead of coming to maturity in the following generations, the ethically-rational life-ideal put forward by Socrates succumbs to an incurable decline, because the notion of pleasure, which lives in it, denies itself as soon as it makes any attempt to think itself out.

Aristippus (_c._ 435-355 B.C.), the founder of the Cyrenaic school, Democritus of Abdera (_c._ 450-360 B.C.), the author of the atomic theory, and Epicurus (341-270 B.C.) seek to retain as much as possible of the positive notion of pleasure. The Cynic school of Antisthenes (born _c._ 440 B.C.), and the Stoicism which originated with Zeno, a native of Kittium in Cyprus (_c._ 336-264 B.C.),

keep from the very beginning to the negative notion._(_6_)_ But the final result is the same with both. Epicurus sees himself compelled at last to exalt the [pg 037] absence of desire for pleasure as being itself the purest pleasure, landing thereby on the shore of resignation where the Stoics take their exercise. The fundamental difference between the two great philosophical schools of antiquity does not lie in what they offer to men as ethical. About what the “wise man” does and leaves undone, they both frequently express themselves in the same way. What separates them is the world-view with which their ethic is combined. Epicureanism accepts the atomistic materialism of Democritus, is atheistic, asserts that the soul perishes, and is in every respect irreligious. Stoicism is pantheistic.

With Epicurus and Zeno ethics no longer trust themselves, as with Socrates, to maintain an independent existence. They see the necessity of attaching themselves to some sort of world-view. Travelling along this road, Epicurus is guided solely by the effort after veracity. He leaves the talking to the purely scientific knowledge of the world, not allowing ethics to join in the investigation of Being and introduce into it what might be of advantage to itself. How poor, or how rich, it will finally become is to him a matter of indifference. The one thing he is concerned about is that the world-view be a true one, and therein lies the greatness of Epicurus with its claim to our respect.

Stoicism seeks to satisfy the need for an inward, stable world-view; like the Chinese monists it tries to find a meaning in the world. It tries to widen out the ethical rationalism of Socrates into cosmic rationalism. The moral is to show itself to be conduct agreeable to the pronouncements of world-reason.

Stoicism has a vision of an optimistic-ethical affirmation of life, grounded in the nature of the cosmos, but it fails to reach it. It is not untutored enough to acquiesce in the ethical simplicity of a nature-philosophy such as can be seen in Lao-tse and in the older philosophical Taoism. It is ever struggling to discover in world-reason the notion of purposive activity, and is ever mercilessly thrust back upon that of activity pure and simple. Hence the ethic with which it is operating never has a sufficiently universalist [pg 038] character to let it form a natural connexion with world-reason. As might be expected from its origin, it is dominated by the problem of pleasure and not-pleasure, and therefore no longer possesses any efficacious instinct for effort. Its horizons, because still determined by the questions arising out of ancient citizenship and the ancient city-state, are narrow. It is, therefore, not advanced enough to engage in thought on nature-philosophic lines, concerned with both the world and man, although it does feel the inner necessity for doing so.

The vacillation which is characteristic of Stoicism comes, then, from the fact that the results it attains to do not match its aspirations, but are much poorer than the latter. The spirit of antiquity tries to find an optimistic-ethical life-affirmation in nature-philosophy, and to find in it also the justification of those instincts for reliable activity which it has possessed since the days when it was entirely untutored, but it cannot do so. Whenever it acknowledges what has happened it sees clearly that thinking about the universe leads only to resignation, and that a life in harmony with the world means quiet surrender to being carried along in the flood of world-happenings, and, when the hour comes, sinking into it without a murmur.

Stoicism talks, it is true, with deep earnestness of responsibility and duty, but since it cannot draw either from nature-philosophy or from ethics a well-established and living notion of activity, it shows us in these words nothing but beautiful corpses. It is impotent to command anything whatever that is bound up with voluntary activity which is conscious of its aim. Again and again evidence breaks through that its thinking has been pushed aside on to the track of passivity. Nature-philosophy only provides the cosmic background for the resignation to which ethics have come. The ideal which gives life to Chinese Monism, of the perfecting of a world through ethical and ethically organized mankind, is not really discerned, much less securely grasped.

One watches with dismay the shaping of the fate of [pg 039] ancient ethics in Epicureanism and Stoicism. In place of the vigorous life-affirming ethic which Socrates expects from rational thinking, resignation steps in. An inconceivable impoverishment takes place in the representation of the moral. The notion of action cannot be worked out to completion. Even so much of it as, thanks to tradition, still survives in the simple thought-methods of the Greek world in general, is lost.

The ancient Greek was more citizen than man. Active devotion to the cause of the community was to him a matter of course. Socrates presupposes it. In the conversations which Xenophon hands down to us in the _Memorabilia_ he is ever insisting on it that the individual must improve himself in order to become an active citizen. The natural course would have been that the thought which originated with him should deepen this mentality by setting before it the highest social aims. It was, however, never at all in a position to maintain the mentality as it received it. More and more it leads the individual to withdraw himself from the world and from all that goes on in it.

By a never-ceasing process of change the ethics of Greek thought become in Epicureanism and Stoicism ethics of decadence. Not being capable of producing ideals of progressive development for collective bodies, they are also impotent to become really ethics of civilization. In place of the ideal of the man who works for civilization they set the ideal of the “wise man.” It is only the inward individual civilization of refined and reflective self-liberation from the world that now floats before its eyes, but this in all its depth.

It is true that there is power in the preaching of resignation which ancient thought, now become knowing about life, allows to go forth to mankind. Resignation is the lofty porch through which one enters upon ethics. But Epicurus and the Stoics stop in this porch. Resignation becomes for them an ethical world-view. Hence they are incapable of leading ancient society from its untutored life- and world-affirmation to one based on thought.

[pg 040]

The conception of the rationally pleasurable, which was the legacy of Socrates, is not productive enough to keep a world alive. It is impossible to develop out of it the ideas of a utilitarianism directed to the welfare of the community, although he believed he found them in it. Ethical thought remains confined within the circle of the self-regarding. Every attempt to ennoble the rationally pleasurable ends in life-affirmation changing into life-denial. On this logical fact was wrecked the ancient West, which, after the critical awakening of the Greek spirit, could have been saved only by means of a reflective optimistic-ethical world-view. It was able to develop seriously what Socrates gave it, but not to make it capable of producing life and civilization.

Plato’s abstract basic principle of the ethical. The ethic of world-negation

Plato, too (427-347 B.C.), and Aristotle (384-322 B.C.), the two great independent thinkers of antiquity, are incapable of producing an ethic of action, and so giving civilization a firm foundation.

Plato seeks the general notion of the Good, but he abandons the path which was pointed out, even if not followed to the end, by Socrates, viz. the determination of it by a process of induction. He gives up trying to arrive at the nature of the Good by considerations of the kind, the object, and the results of action, that is to say, by its content. He wants to establish it by a purely formal process, by abstract logical thinking.

In order to arrive at an ethic he uses a detour through the theory of ideas. All similar phenomena, he says, are to be conceived of as varying copies of an original—to express which he uses the word “idea.” In trees there is to be seen the idea of tree, in horses, that of horse. The idea does not come to us, as we are inclined to think, by our abstracting from trees the idea of tree, and from horses that of horse. We have it within us already. It originates, not in our [pg 041] experience of the empirical world but in the recollection which our soul brought with it from the supra-sensuous, pure world of ideas, when it began its existence in a body. In the same way we have brought with us the idea of the Good.

Thus in a tortured doctrine which is disfigured everywhere with fancies and obscurities, Plato tries to found ethics on a theory about the character of our knowledge of the world of sense, and he is encouraged to this undertaking by the consideration that it is not from reflexion that we obtain our conception of the Beautiful, which is closely allied with that of the Good: we bring that conception also with us, ready made.

Plato is the first of all thinkers who feels that the presence of the ethical idea in man is what it is: something profoundly puzzling. That is his greatest distinction. Hence he cannot profess to be satisfied with the attempt of the historic Socrates to explain the Good as that which is rationally pleasure-giving. It is clear to him that it is something unconditional, with a compelling force of its own, and to preserve for it this character seems to him, as later to Kant, to be the great task of thought.

But what is the result of his undertaking? A fundamental principle for ethics which is devoid of content. In order to secure its lofty character it is allowed to be born of abstract considerations in the country of the supra-sensuous. It can, therefore, never find itself at home in reality and become familiar with it, nor can any rules for concrete ethical conduct be developed from it. Thus Plato, when he treats practically of ethics, is compelled to abide by the chief virtues, as popularly conceived. In the _Republic_ he names four of them: wisdom, courage, temperance, and justice, and he founds them not on his general idea of the Good, but on his psychology.

But the characteristic ethic of Plato has nothing whatever to do with such virtues. If the conception of the Good is supra-sensible and the immaterial world is the only real one, then it is only thought and conduct which deal with the [pg 042] immaterial that can have any ethical character. In the world of appearance there is nothing of value to be made actual. Man is simply compelled to be an impotent spectator of its shadow-play. All willing must be directed to enabling oneself to turn away from this, and get sight of that

true activity which goes on in the light.

The true ethic, then, is world-negation. To this view Plato was committed the moment he allowed the ethical to find its home in the world of pure Being. Thoughts of ascetic inactivity find expression in him side by side with the Greek feeling for reality, and it is confusing that he does not recognize the conflict between them, but speaks now in one sense, now in the other. His ethic is a chaos, and he himself an expert in inconsistency.

Plato's ethic of world-denial is not an original creation; he takes it over in the Indian setting in which it is offered to him by Orphism and Pythagoreanism. By what route there found its way into Greek thought this pessimism which has been thought out to a system and provided with the doctrine of re-incarnation, we do not know, and shall probably never learn. The presence side by side in Greek thought of an artless optimism and a mature pessimism will always remain for us the great puzzle of Greek civilization. But if the pessimism had not been there, Plato must have introduced it. The abstract basic principle of morality which he adopts in order to preserve the absolute character of morality which he was the first to pronounce to be a necessity, precludes any other content than that of the denial of the sensible world and of natural life.

Aristotle. Instruction about virtue in place of ethics

Plato's fate alarms Aristotle. He refuses to soar to the heights where Plato lost himself. How then does he fare?

His object is the establishment of a serviceable ethic which is in harmony both as to extent and content with reality. What he accomplished lies before us in the [pg 043] so-called _Nicomachean Ethics_, the comprehensive work which he composed for the benefit of his son, Nicomachus. The general thought of Socrates, that ethics are a striving after happiness, he acknowledges. But at the same time he makes quite clear his opinion that the part played by activity in ethics must be a much more important one than is given to it in Plato or in the other post-Socratics. Aristotle feels that the crux of the question is the conception of activity, and this he wants to save. He therefore avoids Plato's paths of abstract thinking, and rejects the ethic of pleasure and not-pleasure over which the Cyrenaics and Cynics work so hard. In his ethical thinking the vitality of the ancient world tries to find expression.

In magnificent fashion he lays down the pre-suppositions which are necessary for the carrying through of his undertaking. He finds the motive to activity in the conception of pleasure, a thing he can do because his whole philosophy has indeed for its aim and object the conceiving of Being as formative activity. Hence the essential element in human nature also is activity. Happiness is to be defined as activity in accordance with the law of excellence. Rational pleasure is experience of the perfecting of one's activity.

Starting from the conception of pleasure which experiences itself as activity, Aristotle is on the way to comprehend ethics as deepened life-affirmation, and to attack the problem of leading the ancient world up from a naïve and unreflecting world-affirmation to a thinking one. But on the way he diverges from the high-road.

When he has to ask the decisive question as to what make activity moral, he shrinks from discussing the problem of the basic principle of the moral. Ethics are not some sort of knowledge which gives a content to activity, he says in opposition to Socrates. The content of the will is already given. No reflexion and no knowledge can put anything new into it, or alter it.

Ethics consist, then, not in a guiding of the will by aims and objects which knowledge puts before it, but in the will's [pg 044] own regulation of itself. The right thing to do is to establish the correct balance between the different elements in the given contents of the will. Left to itself, the latter rushes to extremes. Rational reflexion keeps it in the correct middle path. Thus brought to a state of harmony, human activity can be conceived as motived and ethical. Virtue, therefore, is readiness to observe the correct mean which is to be acquired by practice.

Instead of creating an ethic, Aristotle contents himself with a doctrine of virtue. This depreciation of the ethical is the price he pays in order to reach an ethic which ends neither in the abstract nor in resignation. While he shirks the problem of the basic principle of the moral, he still remains able to establish an ethic of activity, though the latter contains indeed no live forces, only dead ones.

Aristotle's ethic is therefore an æsthetic of the impulses of the will. It consists in a catalogue of virtues and in the demonstration that they are to be conceived as a mean. Thus courage lies between rashness and cowardice, temperance between sensuality and insensibility, truthfulness between boastfulness and irony,_(_7_)_ liberality between prodigality and avarice, high-mindedness between conceit and small-mindedness, gentleness between quarrelsomeness and characterless good-nature.

On this excursion through the field of the ethical, there open up many interesting views. In an acute and living discussion Aristotle lets his readers survey the questions of the relations of man to his fellow-men and to society. How much that is deep and true there

is in the chapter on moral excellence and in that on friendship! How he wrestles with the problem of justice!

No one can fail to feel the charm of the _Nicomachean Ethics_. There is revealed in them a noble personality with abundant experience of life, depicted with a magnificent simplicity. But just in proportion as the method followed [pg 045] is advantageous technically, it is valueless in itself. The ethical is reconciled with reality without having first tried to come to clear understanding of itself. It is in this reconciliation that the understanding is to be found, so Aristotle thinks, but he is mistaken. His mind is seduced through his having observed that some virtues—but even these more or less under compulsion—allow themselves to be conceived as real means between two extremes, and he is misled into developing on these lines the whole of his ethical system.

But a more or less natural quality, which in ordinary speech is called a virtue, is one thing, virtue in the really ethical sense is another. The middle quality between prodigality and avarice is not the ethical virtue of liberality, out the quality of rational economy. The middle quality between rashness and cowardice is not the ethical virtue of courage, but the quality of rational prudence. The combination of two qualities only produces a single one. But virtue, in the ethical sense, means a quality guiding itself by an ideal of self-perfection, and being serviceable for some object which looks towards the universal. Liberality as an ethical virtue means a process of spending which serves some object recognized by the person practising it as valuable in principle, and in such a way that any natural tendency to prodigality, should there be such in the giver, plays no part, while the tendency to avarice is paralysed.

Devotion of one's property or one's life to an object which is valuable in principle is under all circumstances ethical, while prodigality and avarice, rashness and cowardice as simple qualities not inspired by any higher aim have never any ethical character; they are merely something natural. Whether the devotion of one's property or of one's life for an object valuable in principle is made more completely than need be or exactly to the extent required by the circumstances, does not alter in any way the ethical character of the decision and the action. Such excess or defect only shows how much or how little the ethical will has allowed [pg 046] itself to be at the same time influenced by considerations of prudence.

Aristotle's representation, then, rests on the fact that he allows virtue in ordinary speech and virtue in the ethical sense to get mixed up. He smuggles in the really ethical, and then offers it as the resultant of two natural qualities, each of which is an extreme.

In the chapter on temperance—_Ethics_, Bk. III., 10—he has to allow that the theory which makes the ethical a mean between two extremes cannot be carried through completely. The love of beauty, he says plainly, however strong it becomes, remains what it is; there can never be any question of excess. He throws out this admission without seeing that he thereby undermines his feeble definition of the ethical as the appropriate relative mean, and, like Socrates and Plato, acknowledges that there can be something which its content allows to be reckoned as good in itself.

Aristotle is so firmly resolved not to let himself be entangled in the problem of the basic principle of ethics, that he will allow nothing to lead him to the discussion of it. He means to voyage along the coast, keep to facts, and deal with ethics as if they were a branch of natural science. Only he forgets that in science we can confine ourselves to venturing from definite given happenings through hypotheses to the nature of the Being which lies behind them, while in ethics, on the contrary, we have to establish a basic principle through the application of which we secure our happenings.

It is because he misunderstands their nature that Aristotle cannot help ethics forward. Plato rides off over the head of Socrates and loses himself in abstractions. Aristotle, in order to maintain the connexion with reality goes down below Socrates. He brings together material for a monumental building, and runs up a wooden shack. Among teachers of virtue he is one of the greatest. Nevertheless, the least of those who venture on the search for the basic principle of the ethical, is greater than he.

[pg 047]

Ethical theory is no more ethics than cartilage is bone. But how strange is this inability to establish the basic principle of ethical action which Socrates regarded as the certain, and from the very first sure and certain, product of thoughtful reflexion on the ethical! Why do all the ancient thinkers who in succession to Socrates search for it, always miss it? Why does Aristotle cease to concern himself with it, and so condemn himself to a doctrine of virtue in which, as a matter of fact, there is hardly any more living ethical force than there is in the abstract ethical system of Plato or in the ethics of resignation of the rest?

The Ideal of the Civilized State in Plato and Aristotle

How little Plato and Aristotle are capable of establishing an ethic of action can be seen from the way in which they sketch their ideal of the civilized State. Plato develops his in the _Republic_, Aristotle his in the _Politics_. At this very time, Mencius (Meng-tse) is

putting before the princes of China a doctrine of the civilized State.

That the State must be something more than a union which regulates in the most practical way the common life of a number of persons whom natural conditions compel to depend upon one another, is quite clear to both of them. They also agree in demanding that the State shall promote the true prosperity of its citizens. This is, however, unthinkable and impossible without virtue, and the State must therefore develop into an ethical institution. “Honourable and virtuous conduct is the object which the political community aims at,” is the way Aristotle puts it.

The State, which is given by history, is therefore to come under the influence of a representation of its nature as a political body which is both ethical and rational. In the _Republic_ Plato puts in the mouth of Socrates the following sentiment: “Unless it happen that either philosophers acquire the kingly power in States, or those who are to-day called kings and potentates cultivate philosophy truly and sufficiently, and thus political power and philosophy [pg 048] become as one . . . there can be no deliverance from evil for States, nor ever, so I think, for the human race” (Bk. V, 473, C and D).

When, however, it comes to a more detailed carrying out of the ideal of the civilized State, Plato and Aristotle betray remarkable embarrassment. First of all, their vision of the State of the future is not that of a community which embraces a whole nation, but is always just a copy of the Greek city-republic with appropriate improvements. That they think out their ideal within such narrow limits is historically intelligible, but for the development of the philosophical idea of the civilized State it is deplorable.

One result of these narrow limits is that both are anxiously concerned to provide that the well-being of the city-republic shall not be endangered by the increase of the population. The number of the inhabitants is to be kept as far as possible always near the same figure. Aristotle is not frightened by the proposal that weakly children shall be allowed to die of hunger, and that unborn children shall be got rid of by intentional abortion. That the Spartan State, on the contrary, regards the increase of the population as desirable, and exempts a citizen from all imposts as soon as he has four children, does not seem to him to be reasonable.

Again, just as these two thinkers cannot work themselves up to a general idea of a national State, so they are unable to reach the idea of mankind. They make a strict line of division between the unfree on the one side, and the free on the other. The former they regard merely as creatures made for work, who are to maintain the material well-being of the State. What becomes of them as human beings is to them a matter of very little interest. Such beings as they are not meant to have any share in the growth towards perfection which is to be brought about by means of the civilized State.

Slavery was, indeed, attacked now and again by the Sophists from their point of view, not, however, on the [pg 049] ground of humanity but from a desire to raise doubts about the accepted justification of existing institutions. Aristotle defends it as a natural arrangement, but recommends kindly treatment.

Artisans, and in general all who earn their living by the labour of their hands, are not to be allowed to be citizens. “One cannot practise virtue, if one leads the life of an artisan, or of one who labours for pay,” says Aristotle. An ethical valuation of labour as such is still something unknown to him, even though he conceives of happiness as “activity in accordance with the law of excellence.” Plato and he are still entirely under the influence of the ancient view that only the “free” man can have full value as a man.

In details of the ideal of the State, however, the two part company, and Aristotle argues against Plato, though, unfortunately, just those parts of the _Politics_ in which he sketches his ideal State have not come down to us complete. The main difference is that Aristotle keeps closer than Plato to the historically given. He builds his State upon the family; Plato makes the State into a family. In his _Republic_ the free men live with property, wives, and children owned in common. They are to possess nothing as their own, so that they may not by private interests be held back from working for the general welfare. Moreover, the general welfare allows the State to breed its citizens systematically. He prescribes the connections which men and women are to form, and permits only such as allow the expectation of a new generation which is sound both in body and mind. The offspring of unions not approved by the authorities are either to be killed before birth, or got rid of by starvation.

Aristotle contents himself with guaranteeing the quality of the offspring by legal regulation of the age for marriage. Women may get married at eighteen, men not till they are thirty-seven. Moreover, marriages are to take place preferably in winter, and as far as possible, when the wind is in the north.

[pg 050]

In what, then, does the good consist which is to be realized by this civilized State? To this decisive question Aristotle and Plato have in reality only the answer that it is meant to make it possible for a number of its members, viz. the “free” men, to devote themselves entirely to their own bodily and mental culture free from care about material things, and to take the lead in public affairs. It is not established with a view to the production of anything ethical in any deeper sense, nor for the sake of an ideal of progress on lines which could be described as in any sense great and noble. Nowhere do the characteristic limitations of ancient ethics reveal themselves so clearly as in the poverty of their ideal of the State.

The ethical valuation of man as man has not yet been reached. Hence the State has for its object, not the growth to perfection of all, but only that of a particular class.

The nation, too, is not yet recognized as a great entity both natural and ethical, and therefore no consideration is given to the question of uniting the various city communities for the joint pursuit of higher objects. Each remains isolated. Plato thinks he has satisfied the claims produced by membership of the same nation by requiring that in wars waged by Greek States against one another the houses shall not be destroyed nor the fields laid waste, as if the war were against barbarians.

The idea of humanity as a whole has not yet come in sight. It is, therefore, not possible for Plato and Aristotle to make their State work in co-operation with others to promote the general progress of mankind.

They therefore establish their civilized State on a type which is hemmed in in every direction by narrow horizons. Moreover, the political community which they adopt as the type is at the very time when they are writing already a dying entity. While Aristotle is writing his _Politics_, his pupil, Alexander the Great, is founding an empire, and Rome is beginning to subject Italy to her rule.

More important still than all external faults in their ideal [pg 051] of the civilized State is the fact that these two thinkers are unable to introduce into the community the energies which are needed for its maintenance. The idea of the civilized State is present with the vitality needed, only when the individual is by the impulse contained in his world-view moved so far as to devote himself to organized society with enthusiastic activity. Without civic idealism no civilized State! But to assume anything of that kind in the members of their State is impossible for Plato and Aristotle, since both have already reached the ideal of the wise man who withdraws himself prudently and gracefully from the world.

Plato admits this. His wise citizens who are destined to be rulers devote themselves to the service of the State only when their turn comes, and are glad when they are set free and can again in retirement busy themselves, as wise among wise, with the world of pure Being.

Aristotle, when he raises in the _Politics_ the question whether the contemplative life is not to be preferred to that of political activity, decides in theory in favour of the latter. “It is a mistake,” he says, “to value inactivity higher than activity, since happiness consists in activity.” But in the doctrine of virtue in the _Nicomachean Ethics_ there is nothing which could lead the individual to place his life at the service of the community.

Plato and Aristotle cherish undoubtedly the ancient conviction that the individual ought to devote himself to the State, but they cannot find a foundation for it in their world-view. Like Epicurus and the adherents of the Porch, they are under the spell of an ethic in which there is present no will to attempt a transformation of the world.

How much greater than the two Greeks is Mencius, when he is thinking out the ideal of the civilized State! He can make it as large as he likes and take men into its service with their best thoughts, because it results in the most natural way from a large-scale world-view of ethical activity.

Plato and Aristotle, lacking such a world-view, can do no more than guess at the nature of a civilized State, and invent one for themselves. Plato’s _Republic_ is a mere [pg 052] curiosity. Aristotle’s _Politics_ is valuable, not on account of the theory of the civilized State which is there presented, but only for his magnificent practical analysis of the advantages and disadvantages of the various State-constitutions, and of their economic problems.

The decadence of antiquity does not begin, then, with the suppression of the individual by the Empire, and its destruction of the normal mutual relations between the individual and the community. It sets in immediately after Socrates, because the ethical thinking which started with him cannot really lead the individual beyond himself, and set him as an effective force in the service of the moralization and the perfecting of social relations.

There is no middle term between the ethic of enthusiasm and that of resignation. But an ethic of resignation cannot think out, much less bring into existence, a system of social relations which can be called really civilized.

Seneca, Epictetus, and Marcus Aurelius

“In imperial times Stoicism shrivels up into a moralizing popular philosophy” is what we are usually told in treatises about ancient philosophy. As a matter of fact what we have to deal with is by no means a shrivelling up, but a serious struggle for a living ethic which begins unexpectedly in the later period of Græco-Roman thought, and leads to an optimistic-ethical nature-philosophy.

The pillars of this movement are L. Annæus Seneca (4 B.C.—A.D. 65), Nero’s teacher, who at the command of his pupil had to open his veins; the Phrygian slave, Epictetus (born _c_. A.D. 50), who in A.D. 94 was with all philosophers banished from Rome by Domitian; the Emperor Marcus Aurelius (A.D. 121-180) who, brought up by pupils of Epictetus, defends the Empire at a time of great danger, and writes his philosophical _Meditations_ while in camp._(_8_)_

[pg 053]

In their classical period Greek ethics offer us either egoistic considerations of advantage, or cold doctrines of virtue, or ascetic renunciation of the world, or resignation. In whichever direction they turn, they never lead men out beyond themselves.

In Seneca, Epictetus, and Marcus Aurelius, they lose this self-regarding character. Renouncing the spirit of the earlier time they develop to an ethic of universal brotherhood, and busy themselves with the immediate, altruistic relations of man to man.

Whence comes this understanding for humanity, which is never seen in classical antiquity?

The older Greek moralists are concerned with the State. Their interest is absorbed in the maintenance of the organization of society which is embodied in the city-republic, so that the free citizens can continue to live the life of freedom. The type of complete manhood is to be realized. All around there is the activity of men who receive no consideration except so far as they are means to this end.

But amid the mighty political and social revolutions which lead to the creation of the Empire this mentality ceases to be accepted as a matter of course. The fearful experiences it goes through cause feeling to become more human, and the horizons of ethics are widened. The city-republic, on which ethical thinking had been built up, has disappeared, but an empire now crushes men down just in the same way. Thus the individual man as such becomes the object of reflexion and of ethics. The conception of the brotherhood of all men appears. A disposition to humanity makes itself heard, and Seneca condemns the gladiatorial shows. Nay more: even the [pg 054] inner relationship between mankind and the animal world is recognized.

So now when they have caught sight of mankind as a whole and man as such, ethics reach such a depth and breadth as allows them to try to comprehend themselves in a universal world-will. Henceforth nature-philosophy and ethics can work together. Stoicism had from the very beginning a vision of this, but had not been able to make it a reality, since it had not at its disposal the needful living and universalist ethic.

But there is another reason why optimism and ethics can now in nature-philosophy come into power. The old school of the Porch was crushed down into resignation just in proportion as it submitted to the necessity for critical thinking. But as time goes on, the practical and religious instincts which were always present in its world-view, gain in strength. The antiquity which is passing away is no longer critical, but either sceptical or religious, and therefore the later school of the Porch can let itself be guided by the ethical demands of its world-view much more completely than the old one could. It becomes at once deeper and more simple than the latter, and, like Chinese ethical monism, rises to such freedom from limitations as to be able to interpret the world-will as ethical. So now Stoics appear who, like Confucius, like Mencius, and like Chwang-tse, and indeed, like the Rationalists of the eighteenth century, preach ethics as something grounded in the nature of the universe and of mankind. They cannot prove the truth of this world-view any better than could Zeno and his pupils, who also resorted to it, but they announce it with an inner conviction which the former could not command, and produce their results by means of an enthusiasm which was denied to their predecessors.

When the later school of the Porch reaches the stage of exalting the world-principle more and more to become a personal and ethical god, it is following laws which are at work also in Hinduism.

[pg 055]

Yet the world-view of resignation, which it has inherited from the older school, it never succeeds in rendering entirely impotent. In Seneca and Epictetus this is still strongly maintained side by side with the ethical conception of the universe. It is only in Marcus Aurelius that the optimistic motives sound victoriously through.

Stoicism was from the beginning a multiform elemental philosophy, and it is because it ventured to be this in such comprehensive measure that the later Stoicism is so rich and so full of life.

Moral Sayings of Seneca

No man is nobler than his fellow, even if it happen that his spiritual nature is better constituted and he is more capable of higher learning. The world is the one mother of us all, and the ultimate origin of each one of us can be traced back to her, whether the steps in the ladder of descent be noble or humble. To no one is virtue forbidden; she is accessible to all; she admits everyone, she invites everyone in: free men and freedmen, slaves, kings, and exiles. She regards neither birth nor fortune; the man alone is all she wants.

It is a mistake to think that the status of a slave affects the whole of a person's nature; the nobler part of it is not touched thereby.

Every single person, even if there is nothing else to recommend him, I must hold in regard, because he bears the name of man.

In the treatment of a slave we have to consider not how much we can do to him without being liable to punishment, but how much the nature of right and of justice allows us to, seeing that these bid us treat gently even prisoners and purchased slaves. Although in the treatment of a slave everything is allowed, there is nevertheless something which through the common right of every living being is stigmatized as not permissible in the treatment of a man, because he is of the same nature as thyself.

This, in fact, is the demand which is laid upon each man, viz. that he works when possible, for the welfare of many; if that is impracticable, that he works for the welfare of a few; failing that, for the welfare of his neighbours, and if that is impossible, for his own.

It is through untiring benevolence that the bad are won over, and there is no disposition so hard and so hostile to loving treatment ... as to refuse love to the good people whom it will in the end have to thank again for something more. "Not a word of thanks did I get! What am I now to begin to do?" What the gods do, . . . who begin to shower benefits on us before we are aware of it, and continue them even though we do not thank them.

Moral Sayings of Epictetus

Nature is wonderful, and full of love for all creatures.

Wait upon God, ye men. When He calls you, and releases you from [pg 056] service, then go to Him; but for the present remain quietly in the position in which He has placed you.

You carry a god about with you, and do not know it, unhappy one! You have him within yourself, and do not notice it when you defile him with unclean thoughts or foul deeds.

Cultivate the will to satisfy yourself, and to stand right before God. Strive to become pure, one with yourself and one with God.

Think silence best; say only what is necessary, and say it shortly. Above all, do not talk about thy fellow-men, either to praise them, or to blame them, or to compare them with others. Do not swear; never, if possible, or at any rate as seldom as possible. Your bodily wants—food, drink, clothing, housing, service—satisfy in the simplest way. Avoid unseemly joking, for there is always a danger of becoming vulgar, and joking away the respect of your fellow-men.

As you are careful when walking not to tread on a nail or to sprain your ankle, so take care not to let your soul get hurt.

Moral Sayings from the Meditations of Marcus Aurelius

Everything that happens, happens right, and if you can observe things carefully, you will recognize that it is so. I do not mean only in accordance with the course of nature, but much more that they happen in accordance with the law of righteousness, and as if controlled by a Being who orders all things according to merit.

If I am active, I am so with due regard to the general welfare. If anything happens to me, I accept it and consider it in relation to the gods and the universal source from which, in close connection, come all our happenings.

He who commits unrighteousness is godless, for universal nature created rational beings for one another; to help each other where there is need, but never to injure one another.

Love mankind; obey the godhead.

If thou art unwilling to get up in the morning, reflect thus: I am waking in order to go and work as one of mankind.

Seek all thy joy and contentment in advancing, mindful always of God, from one generally useful deed to another.

The best way to avenge oneself on anyone is to avoid returning evil for evil.

It is a privilege of man to love even those who do him wrong. One can reach this level by reflecting that all men are of one family with oneself; that their shortcomings are due to ignorance, and against their will; that in a short time both of you will be dead.

What is good is necessarily useful, and that is why the good and noble man must be concerned about it.

Nobody gets tired of seeking his own advantage. But doing so procures us an activity which is natural. Never get tired, then, of seeking thine own advantage, provided thou procurest thus the advantage of others also.

[pg 057]

Treat as befits a man endowed with reason, that is magnanimously and nobly, the animals which are not so endowed, and indeed all creatures whatever that can feel but have no reason. But other men, since they are endowed with reason, treat with friendly affection.

Thou has existed till now as a fragment of the universe, and wilt some day be absorbed in thy producer, or rather, thou wilt suffer a transformation and reappear as a new germ of life.

Many grains of incense are destined for the same altar. Some fall soon into the flame, others later, but that makes no difference.

The Optimistic-Ethical World-View of the later Stoicism

In their optimistic-ethical world-view the later Stoics find those impulses to effort which were not available for the ancient ethics of the classical age. Marcus Aurelius is an enthusiastic utilitarian like the Rationalists of the eighteenth century, because, like them, he is convinced that nature itself has bound up together what is ethical and what is advantageous to the individual and to the community.

That being so, the classical question of ancient ethics whether the thinking man is to busy himself with public affairs or not must again be discussed. Epicurus taught that “the wise man has nothing to do with State affairs unless exceptional circumstances arise.” Zeno’s decision was that “he will take part in the business of the State unless obstacles prevent it.” Both schools leave the retirement into oneself to the decision of the Wise man, only one lets the grounds for the decision be given somewhat earlier, the other somewhat later. The thought of a devotion to the general good which is to be kept active for its own sake and under all circumstances is outside the circle of vision of their ethic.

With the later Stoics it emerges, because the conception of “mankind” has come in sight. Man, as Seneca works out in his treatise on Leisure (_De Otio_), belongs to two republics. One is a large and universal one, extends as far as the sun shines, and embraces both gods and men; the other is that into which through the fate assigned us by our [pg 058] birth, we have been adopted as citizens. Circumstances may bring it about that the wise man cannot dedicate himself to the service of the State, but, to escape the storm, must “take refuge in the harbour.” It may happen—and Seneca has in mind his own time—that not one of existing States is of such a character as to put up with the activity of the wise man. Nevertheless, the latter does not wholly withdraw into himself, but he serves the great republic by working to improve the general outlook of mankind, and to hasten the coming of a new age.

In Epictetus also this deepened and widened notion of duty is to be found. Marcus Aurelius does not even consider any impossibility of taking part in public life. In him there speaks the ruler who feels himself to be the servant of the State. His ideal is the citizen who “from one activity which makes his fellow-citizens happier goes on to another, and undertakes with alacrity anything whatever that the State lays upon him.” “Do what is needed, and what is bidden by the reason of a being who is destined by nature to membership of a State, and do it as it is bidden.”

In the middle of the second century A.D. ancient thought arrives at an optimistic-ethical world-view which holds within itself living ideals of civilization, and therefore anticipates those which later on in the eighteenth century will bring into activity so mighty and universal a movement of civilization. But for the men of the Græco-Roman world it comes too late. It does not permeate the masses, but remains the private possession of an _élite_.

It cannot permeate the masses, because there are forces at work among them with which it cannot combine. It is true, indeed, that the ethic of the later Stoicism is so near akin to the universal charity of the Christian ethic, that by the tradition of later times Seneca is declared to be a Christian, and that the Church father, Augustine, holds up the life of the heathen emperor, Marcus Aurelius, as an example for Christians.

Yet the two movements cannot amalgamate, but have [pg 059] to fight each other. Marcus Aurelius is responsible for most terrible persecutions of Christians, and Christianity on its side declares war to the knife against the Porch.

Why this strange fatality? Because Christianity is dualistic and pessimistic, the ethic of Stoicism is monistic and optimistic. Christianity abandons the natural world as evil, the later Stoics idealize it. It helps not at all that their ethical teaching is almost identical. Each appears as part of a world-view which is irreconcilable with that of the other. All contradictions in the world may be concealed, but not that between two world-views, and the struggle ends with the annihilation of the optimistic-ethical world-view of the Stoics, which is defended by officers without an army. The attempt that was undertaken as the ancient world was coming to an end, to restore the Empire and make it an empire as wide as mankind, was a failure.

The horizons of the philosophy of the ancient world had remained narrow too long. No ethical thinkers had appeared who at the right time might have led that world to an ethical optimism about reality. It was a calamity, too, that the natural sciences, which had started in such a promising way, came to a standstill, partly through the fault of fate, partly because philosophy turned away from them, before mankind discovered the law of the uniformity of nature, and obtained thereby control over it. Hence the men of antiquity never acquired that self-consciousness which in their descendants of modern times has kept alive, even through the darkest periods of history, the belief in progress—even though it be sometimes progress of the most superficial kind. This psychological factor is of great importance.

It is true that artistic ability, which in the Greek spirit meets us in such abundant measure, is also control over the material, but this creative power was unable to draw the man of antiquity up to a higher life-affirmation and to belief in progress. It served only to let him express himself, in words and in form, in the antagonism between primitive [pg 060] world- and life-affirmation, and thinking world- and life-denial. It is the puzzling intermixture of serenity and melancholy which produces the tragic charm of Greek art.

From every point of view, then, a strong ethical world- and life-affirmation is made difficult for the ancient world. It therefore falls more and more a prey to pessimistic world-views, which draw its thoughts away from reality, and celebrate the liberation of the spiritual from its bondage to the material in a succession of cosmic dramas. Gnosticism, Oriental and Christian, Neo-Pythagoreanism, which arose as early as the first century B.C., the Neo-Platonism which originated with Plotinus (A.D. 204-269), and the great Mystery-religions, all come to meet the religious, world-shunning disposition of the masses during the breaking-up of antiquity, and offer it that deliverance from the world of which it is in search. In this chaos of ideas Christianity emerges victorious because it is the most robust religion of redemption, because as a community it possesses the strongest organization, and because beneath its pessimistic world-view it has at its disposal living ethical ideas.

The optimistic-ethical monism of the later Stoics is like a sunbeam breaking through in the evening of the long, gloomy day of antiquity while the darkness of the middle ages is already drawing on, but it has no power to waken any civilization to life. The time for that is past. The spirit of antiquity, having failed to reach an ethical nature-philosophy, has become the prey of a pessimistic dualism in which no ethic of action is any longer possible; there can only be an ethic of purification.

The thoughts of Seneca, Epictetus, and Marcus Aurelius are the winter seed of a coming civilization.

[pg 061]

CHAPTER VI

OPTIMISTIC WORLD-VIEW AND ETHICS IN THE RENAISSANCE AND POST-RENAISSANCE PERIODS

Belief in Progress and Ethics

THE essential characteristic of the modern age is this, that it thinks and acts in the spirit of a world- and life-affirmation which has never before shown itself with such active strength.

This world-view breaks through in the Renaissance, first at the end of the fourteenth century, and it arises as a protest against the mediæval enslavement of the human spirit. The movement is helped to victory by the increasing knowledge of Greek philosophy in its original form which is the result of the migration to Italy about the middle of the fifteenth century of learned Greeks from Constantinople. Among the thinking men of that time there arises the belief that philosophy must be something more elemental and more living than Scholasticism made it.

But the thought of antiquity would not have been sufficient by itself to keep alive this new world- and life-affirmation which appealed to it. It has not, in truth, the mentality required. But another kind of fuel is in time brought for the fire. Taking refuge from book-learning in nature, the men of that time discover the world. As seamen they reach countries whose very existence was not suspected, and they measure the size of the earth. As inquirers they press on into the infinite and the secrets of the universe, and learn by experience that forces governed by uniform laws are at work in it, and that man has power to make them serviceable to himself. The knowledge and power won by Leonardo da Vinci (1452-1519), Copernicus [pg 062] (1473-1543), Kepler (1571-1630), Galileo (1564-1642), and others are decisive for the current world-view.

As a movement which draws its life solely from spiritual forces, the Renaissance passes its bloom-time comparatively quickly, and without forming much fruit. With Paracelsus (1493-1541), Bernardino Telesio (1508-1588), Giordano Bruno (1548-1600), and others, an enthusiastic nature-philosophy announces itself. It does not, however, reach full growth. The Renaissance has not strength enough to bring to birth a world- and life-affirming philosophy corresponding to their spirit. Here and there their thought surges for a time, like a rough sea, against the world-denying world-view of the Church. Then all is still. What we know definitely as the philosophy of modern times begins almost without any reference to the Renaissance. It springs not from any nature-philosophy, but from the problem of the theory of knowledge which was raised by Descartes, and from that starting-point philosophy has once more had laboriously to seek its way to a nature-philosophy.

It is not, then, because it was enlarged during the Renaissance into a fully thought out world-view that world- and life-affirmation made good its position in the modern age. If it was able to hold out right into the eighteenth century, when it triumphs against the world- and life-denial which mediæval thought and Christianity kept working in opposition to it, it owed this to the circumstance that progress in knowledge and power never ceased. In them the new mentality had a support which never gave way, but became continually stronger. Since the new scientific knowledge cannot be suppressed nor its progress arrested, belief in the power of truth becomes firmly established. Since it becomes more and more evident that nature works with a uniformity which never misses its aim, there grows up a confidence that the circumstances of society and of mankind generally can be so organized as to secure definite objects. Since man is ever obtaining [pg 063] greater power over nature, he takes it more and more as self-evident that the reaching of perfection in other spheres also is only a question of a sufficiency of will-power and a correct way of grappling with problems.

Under the steadily working influence of the new mentality the world-view of Christianity changes, and becomes leavened with the leaven of world- and life-affirmation. It gradually begins to be accepted as self-evident that the spirit of Jesus does not give up the world in despair, but aims at transforming it. The early Christian conception of the Kingdom of God, which was born of pessimism and, thanks to Augustine, prevailed through the Middle Ages, is rendered impotent, and its place is taken by one which is the offspring of modern optimism. This new orientation of the Christian world-view, which is accomplished by a slow and often interrupted process of change between the fifteenth century and the end of the eighteenth, is the decisive spiritual event of the modern age. During this period Christianity takes no account of what is happening to itself. It believes that it is remaining unchanged, whereas in reality, by this change from pessimism to optimism, it is surrendering its original character.

The man of modern times, then, becomes optimistic, not because deepened thought has made him understand the world in the sense of world- and life-affirmation, but because discovery and invention have given him power over it. This enhancement of his self-appreciation and the consequent strengthening of his will and his hopes, determine his will-to-live in a correspondingly pronounced and positive sense.

In the ancient world man’s natural disposition to world- and life-affirmation could not be worked out to a complete world-view of the same, because at that time deep thought about the world and life pressed resignation upon him as a necessity of thought. In the man of the modern age the mentality produced by discovery and invention unites with his natural disposition to world- and

life-affirmation, and establishes him in an optimistic world-view [pg 064] without leading him to deeper thought about the world and life.

The spirit of the modern age is not the work of any one great thinker. It wins its way gradually by reason of the unbroken series of triumphs won by discovery and invention. Hence it is not a result of chance that an almost unphilosophic and moreover somewhat antiquated personality like Francis Bacon, Lord Verulam (1561-1626), is the man who drafts the programme of the modern world-view. He founds it upon the sentence: “Knowledge is power.” His picture of the future he develops in his _New Atlantis_, in which he describes how the inhabitants of an island, through the practical application of all known discoveries and inventions and all possible rational reflexion on the purposive organization of society, find themselves in a position to lead the happiest possible lives._(_9_)_

Christian and Stoic Elements in Modern Ethics

What is the relation between ethics and the mentality of belief in progress, and how were they influenced by it?

When the ethical thought of antiquity wanted to come to clearness about itself, it fell a victim to resignation, because it tried to determine the moral as that which is rationally profitable and pleasurable to the individual. It remained shut up within the circle of the egoistic, and never reached the thought of social utilitarianism. From such a fate modern ethics are protected in advance. They have no need to produce from their own resources the thought that the ethical is action directed to promoting the welfare of others, for they find it as something already accepted as true. That is the gift of Christianity. The thought of Jesus that the ethical is the individual’s active self-devotion to others has won its way to acceptance. Ethics, [pg 065] which are making themselves independent of religion, keep, as a result of their passage through Christianity, a pronouncedly active and altruistic mode of thought. What they have to do now is to provide this possession with a rational foundation.

It is extraordinarily significant that to meet modern ethics there comes in the Late Stoicism a philosophical ethical system in which there appear, as the result of rational thinking, thoughts which run side by side with Christian morality. There is now coming up for the benefit of modern times the seed sown by Seneca, Epictetus, and Marcus Aurelius. Cicero, too, counts with modern times for so much, because its thinkers find in his writings noble morality based upon thought. The discovery of Late Stoicism’s ethic of humanity is for modern times akin to their discovery of nature. They identify it with the real Christian ethic, and contrast it with the scholastic, in which Jesus is expounded according to Aristotle. It is through Late Stoicism that modern times become aware that the moral is something direct. Because Seneca, Epictetus, and Marcus Aurelius speak to such an extent just as Jesus did, they help to spread the conviction that the truly rational ethic and the ethic of the Gospels coincide with one another.

When antiquity came to an end, Late Stoicism and Christianity, in spite of the identity of their moral teaching, had torn each other to pieces. In modern times they unite in order to produce together an ethical world-view. Why is that now possible which before was impossible? Because the chasm which lay between their respective world-views has been bridged. Christianity now treats world- and life-affirmation as valid.

But how could this volte-face of Christianity be brought about? Because of the fact that in spite of its pessimistic world-view it upholds an ethic which, so far as it touches the relation of man to man, is an activist ethic. The pessimistic world-view, if it thinks itself out to a consistent conclusion, must end with a purely world-denying ethic, [pg 066] divorced from action, as it has in India. The peculiar character, however, of the world-view of Jesus which is determined by the expectation of the end of the world and the coming of a supernatural kingdom of God, together with the directness of his ethical feeling, entail his proclaiming of an ethic of active devotion to one’s fellow-Man in spite of his pessimistic attitude towards the natural world. This activist ethic is what is wanted to provide the cardinal-point of an evolution from a Christian-pessimistic world-view to one of Christian optimism. The modern age, following its instinct, assumes it as self-evident that an ethic which deals with the active relations of man to man is pre-supposed to be an ethic which assigns a positive value to action as such, and, further, that such an ethic of action belongs to a world-view which is optimistic and which wills and hopes for a transformation of relationships.

It is, then, the ethic of active self-devotion taught by Jesus which makes it possible for Christianity to do what is suggested by the spirit of the modern age, and modulate from the pessimistic to the optimistic world-view. This result finds expression in the way the new conception of Christianity, when it has to come to an understanding with the old one, contrasts itself as “the religion of Jesus” with “the Christianity of dogma.”

A way is prepared, then, in Erasmus and individual representatives of the Reformation, shyly at first but then more and more clearly, for an interpretation of the teaching of Jesus which corresponds to the spirit of modern times, an interpretation which conceives the teaching as a religion of action in the world. Historically and in actual fact this is a wrong interpretation, for the world-view of Jesus is, so far as concerns the future of the natural world, thoroughly pessimistic. His religion is not a religion of world-transforming effort, but the religion of awaiting the end of the world. His ethic is characterised by activity only so far as it commands men to practise unbounded devotion to their fellow-men if they would attain to that inner perfection [pg 067] which is needed for entrance into the supernatural kingdom of God. An ethic of enthusiasm, and therefore presumably focused upon an optimistic world-view, forms part of a pessimistic world-view! That is the magnificent paradox in the teaching of Jesus.

But the modern age was right in overlooking this paradox and in assuming in Jesus an optimistic world-view which corresponded to an ethic of enthusiasm and met with a welcome the spirit of Late Stoicism and of modern times. For the progress of the spiritual life of Europe this mistake was a necessity. What crises the latter must have gone through, if it had not been able without embarrassment to place the new world-view under the authority of the great personality of Jesus!

The mistake was such a natural one that till the end of the nineteenth century it was never seriously shaken. When historical criticism, at the beginning of the twentieth century, proclaimed its discovery that Jesus, in spite of his activist ethic, thought and acted under a pessimistic world-view dominated by the expectation of the end of the world, it aroused indignation. It was accused of degrading Jesus to a mere enthusiast, while it after all only put an end to the false modernising of his personality._(_10_)_

What we at the present time have to do is to go through the critical experience of being obliged to think as modern men under a world-view of world- and life-affirmation, and yet let the ethic of Jesus speak to us from out of a pessimistic world-view.

Of this problem which is disclosing itself to-day the early period of the modern age suspects nothing. Jesus and the moralists of Late Stoicism together are its authorities for an ethical world- and life-affirmation.

What the Late-Stoic ethic is for the modern age is shown by Erasmus of Rotterdam (1466-1536), Michel de [pg 068] Montaigne (1533-1592), Pierre Charron (1541-1603), Jean Bodin (1530-1596), and Hugo Grotius (1583-1645), and that whether their ideas run predominantly on Christian or on freethinking lines. To the Later Stoics Erasmus owes it that he can understand the simple gospel of Jesus which was being discovered behind the Church's dogmas, as being the essence of all ethical philosophizing. It is by finding support in them that Montaigne in his _Essays_ (1580) is saved from falling into complete ethical scepticism. Because he is inspired by the Later Stoics, Bodin in his work _De la république_ (1577), puts forward an ethical ideal of the State to combat the ideas of Machiavelli's _Prince_ (_Principe_) (1515). Because he draws from the same source, Pierre Charron in his work _De la sagesse_ (1601), ventures to assert that ethics are higher than traditional religion, and can maintain themselves in an independent position in face of it without losing anything of their essential nature or of their depth. Because the work of Marcus Aurelius has preceded him, Hugo Grotius is able in his famous work, _De jure belli ac pacis_ (1625) to lay so securely the foundations of natural and international law, and thereby to champion the claims of reason and humanity in the domain of jurisprudence.

Other considerations apart, it would have been the first task of the rising power of natural science to restore to currency the world-view of Epicurus, and Pierre Gassendi (1592-1655)_(_11_)_ attempts it. He fails, however, to accomplish his purpose. By its inward belief in progress the mentality of the modern age is driven in elemental fashion beyond scepticism and sceptical ethics. What is great in Epicurus, viz. that in obedience to the deepest demands of truth he tries to think ethically within a nature-philosophy which does not interpret nature as embodying any purpose, can neither be comprehended nor be put before his own age by the philosopher's all too clever modern prophet.

[pg 069]

For the weighty questions of absolute truth that time is by no means ripe. Its capacity is only that of the uncritical. Typical for its spirit is Isaac Newton (1643-1727), who in his investigation of nature is purely empirical, and in his world-view remains simply Christian.

Against the difficulties which crop up for ethics and world- and life-affirmation out of a nature-philosophy which works without any presuppositions, the Renaissance and the Post-Renaissance are secure. The belief in progress which arises from the achievements of discovery and invention, and the joy felt in action itself are their world-view.

Thanks to belief in progress, new life streams into ethics. The inner relations between ethics and world- and life-affirmation begin to have their effect. The elementary impulses to activity which are embodied in the Christian ethic are set free, and the belief in

progress gives them an aim and object: the transformation of the circumstances of society and of mankind.

It is not any really deeper ethical thinking that brings the modern age in, but the influence exerted by the belief in progress, which arose out of the achievements of discovery and invention, on the ethic which drew its life from Stoic and Christian thought. The cart is drawn by the belief in progress, and at first ethics have only to run along beside it. But as the cart gets heavier and the road more difficult to negotiate, so that ethics ought to lend their strength to help, they refuse, because they have no strength of their own. The cart begins to run backward, and carries belief in progress, and ethics with it, down the hill.

The task before philosophy was to change the world- and life-affirmation which arose out of enthusiasm over the attainments in discovery and invention into a deeper, inner one arising out of thought about the universe and the life of man, and on that same foundation to build up an ethical system. But philosophy could do neither.

About the middle of the nineteenth century, when it has become perfectly clear that we are living with a world- and [pg 070] life-affirmation which has its source merely in our confidence in discovery and invention and not in any deeper thinking about the world and life, our fate is sealed. The modern optimistic-ethical world-view, though it has done so much for the material development of civilization, proves to be like a building erected already to a considerable height but on rotten foundations, and has to collapse.

[pg 071]

CHAPTER VII

LAYING THE FOUNDATION OF ETHICS IN THE SEVENTEENTH AND EIGHTEENTH CENTURIES

Hartley, Holbach. Devotion as Enlightened Egoism

MODERN times find world- and life-affirmation so self-evident that they feel no need to give them a sure foundation, and to deepen them, by thought about the world and life. Pessimism they brush aside as reactionary folly, without suspecting how deep down into thought it has sent its roots.

They do, however, see the necessity of establishing the nature of the ethical. How do they proceed to do this?

That the ethical means action directed to promoting the common good is their firm belief from the first, and they are safe from the fate of ancient thought, viz. sticking fast in the mud of resignation while trying to give the ethical a proper foundation. Instead of that they have to answer the question how the unegoistic makes it appearance beside the egoistic, and in what inner relation they stand to each other.

A performance now begins like that which went on after the appearance of Socrates, only the task is proposed this time not by an individual but by the spirit of the time. Another attempt is made to consider the ethical problem in isolation, as if it consisted in reflexions on the relation of the individual to himself and to society, these having no need to settle their position with regard to ultimate questions of the meaning of the world and of life. The ethical problem seems, too, to be a much easier one than it was then, because world-affirmation and activity directed towards the general welfare no longer have to be proved, but appear among the presuppositions which are taken for granted.

[pg 072]

There are three ways in which the relations between the egoistic and the altruistic can be made clear. Either one assumes that the egoistic in the thought of the individual is automatically converted into the altruistic by consistent meditation. Or one supposes the altruistic to have its beginning in the thought of society and thence to pass over into the convictions of the individual. Or one retires to the position that egoism and altruism are both among the original endowments of human nature. All three explanations are attempted, each with most varied arguments. They are not always carried to a conclusion without intermixture, and with many thinkers there is interplay of one with another.

The attempt to deduce devotion to the common welfare from egoism by psychological considerations is made in the most systematic way by David Hartley (1705-1757)_(_12_)_ and Dietrich von Holbach (1723-1789)._(_13_)_

Hartley, a theologian who betook himself to the practice of medicine, claims to see in altruism a purposive ennoblement of original selfishness which comes into play under the influence of rational thought. The much-reviled Holbach ascribes its origin to the fact that the individual, if he rightly understands his own interest, will always form his conception of it in connection with the interest of society, and therefore direct his activities to the latter as well.

Both attempt to carry up their building, so far as it goes, with materialistic considerations and then to roof it with idealist ones. But neither with the coarser nor with the finer considerations nor with both together can the psychological derivation of altruism from egoism produce any convincing result.

The coarser ones do not carry us very far. It is acknowledged, [pg 073] of course, that the prosperity of society depends upon the moral disposition of its members and that the better the moral condition of society the better is the individual's expectation of prosperity. But it does not follow that the individual becomes more moral, the better he understands his own interests. The mutual relation between him and society is not of such a character that he derives benefit from the latter just in proportion as he himself by his moral conduct helps to establish its prosperity. If the majority of its members are with short-sighted egoism intent only on their own good, then the man who acts with wider outlook makes sacrifices from which there is no prospect of gain for himself, even if the best happens and they are not lost without benefiting the community. If, on the other hand, through the moral conduct of the majority of its members the condition of society is favourable, the individual profits by it even if he fails to behave towards it as morality demands. By conduct which disregards both past and future, he will carve for himself an unduly big share of personal prosperity out of the prosperity of the community, milking the cow which the rest feed. The influence of the individual on the prosperity of the community and the reaction of social prosperity on that of the individual do not stand in a simple relation to each other which acts equally in both directions. The consideration, therefore, that egoism, rightly understood, will oblige the individual to resolve on activity which is directed to promoting the common good, is a ship which sails well, but leaks.

The psychological derivation of altruism from egoism must, then, in some way or other, make an appeal to the self-sacrifice of the individual. This it does by inducing him to consider that in happiness there is a spiritual element as well as a material. Man needs (it is said) not only external prosperity, but to be respected by others and to be satisfied with himself, and he can have this double experience only when he concerns himself about the [pg 074] prosperity of others. Even Holbach, who tries to be inexorably matter-of-fact, lets these considerations speak loudly.

The attempt is made, therefore, above the prolonged bass note of the conception of happiness derived from ordinary egoism, to modulate into the spiritualized conception of it.

The path which this attempt has to follow runs parallel to that which led the successors of Socrates into the abyss of the paradoxical. In order to get from egoism into altruism and so think out to a conclusion the ethic of the rationally-pleasurable, the Epicureans wished to use the same scale of values for spiritual and material pleasure alike. The only result was that their ethic transformed itself into resignation. Now again, in modern times, and again for the sake of ethics, spiritual happiness is to be regarded as happiness in the same way as material happiness is, and here again the result is a paradox.

Material and spiritual happiness are not so related that the one can find its continuation in the other. If the second is for the sake of ethics called in with the first, it does not strengthen the first, but paralyses it. The man who does earnestly try to guide himself by the light of spiritual as well as material happiness, ends by finding that the recognition accorded him by his fellow-men, which at first seemed to him to make almost the whole of spiritual happiness, becomes more and more meaningless. It is to him a miserable lump of solder which drops down between material and spiritual happiness without being able to fasten them together. More and more exclusively he experiences spiritual happiness as the condition in which he is at one with himself and therefore can justifiably accord himself a certain amount of self-appreciation.

Spiritual happiness is sufficient unto itself. Either the man is led to resolve on ethical conduct because he expects from it a moulding of the outward circumstances of his being which will bring him profit and pleasure; or he chooses it because he finds his happiness in obeying his inner compulsion to ethical action. In the latter case he [pg 075] has left far behind him all calculations about the interdependence of his morality and his material happiness. The fact that he is a moral man is in itself his happiness, even though it land him in the most disadvantageous situations.

But if spiritual happiness can never be welded into union with material, it is useless trouble to try to depict altruism as an ennobling of egoism.

If the ordinary conception of pleasure, that it may be brought into union with ethics, is submitted to a process of refining, it ends by being refined away. In ancient ethics, in which the refining is done under the influence of an ethical system which is definitely egoistic, it transforms itself into the pleasure of being without pleasure, and allows ethics to end in resignation. In modern ethics, in which the pleasure to be refined is under the influence of altruism, it works itself up into an irrational and immaterialistic enthusiasm. In both cases there is the same paradoxical proceeding, only that in one case it goes in the negative direction, in the other in the positive.

Whenever, then, thought wishes to conceive ethics as springing from pleasure or happiness, it arrives at resignation or enthusiasm, at spiritualised egoistic or at spiritualised expansive conduct.

There is no way in which natural pleasure can, in really deep thinking, be brought into connexion with ethics.

Hobbes, Locke, Helvetius, Bentham

The explanation that altruism is a principle of action which the individual takes over from society is to be found expressed in characteristic ways by Thomas Hobbes (1588-1679),_(_14_)_ John Locke (1632-1704),_(_15_)_ Adrien Helvetius (1715-1771)_(_16_)_ and Jeremy Bentham (1748-1832)._(_17_)_

[pg 076]

Hobbes represents the State as commissioned and empowered by the majority of the individual citizens to engage the whole body in action for the common advantage. In this way alone, he asserts, is it possible to realise the common good in which the egoism of individuals finds the highest possible degree of prosperity. Left to themselves, men would never be able to get free from their short-sighted egoism, and would, therefore, miss prosperity. Their only possible course, then, is to join in setting up an authority which will drive them into altruism.

With external means only, however, organized society cannot engage the individual in all the activities which are needed for the common good. It must strive to ensure its power over him by means of spiritual conviction as well. Locke takes this need into consideration. According to him it is God and society together who force altruism upon the individual by appealing at the same time to his egoism. These two authorities have, that is to say (as our reason enables us to recognize), so ordered the course of things that actions beneficial to society are rewarded, and those injurious to it are punished. God has at his disposal rewards and punishments of endless duration. Society works in two different ways: through the power given to it by the criminal law, and through the law of public opinion in which it uses praise and blame as spiritual means of compulsion. Man being guided both by pleasure and absence of it, he manages to accommodate himself to those rules which defend the general good so effectually, and he thereby becomes moral.

In spite of all their differences on single points, Hobbes and Locke agree in having this external conception of ethics. The essential point of distinction between them is [pg 077] that with Hobbes society alone plies the whip, while with Locke God and society handle it together.

Helvetius, who belonged to a family which had migrated from the Palatinate into France, is more refined and more inward. In his life as a farmer of taxes and a property-owner, he always tried, along with his noble-minded wife, to act with kindness and justice as he explains them in his book. It is clear to him that ethics means somehow or other enthusiastic action, that is, action which springs out of feeling._(_18_)_ Society cannot, therefore, force these virtues into the individual; it can only educate him into them, and it does in fact apply all the means and devices which are at its disposal to influence his egoism in their direction. Above all it makes good use of his striving to win recognition and fame. The praise which it pours on that which is “good” in its own sense of the word is for the mass of men the strongest inducement to take up work for its interests. Helvetius would perhaps have offered a less external conception of how ethical action is realized, if he had not, with the best intentions, taken so much trouble to depict morality as something which can be taught.

In the view that morality is enthusiastic action to which the individual is roused by society, Bentham agrees entirely with Helvetius, but he carries it through in a much deeper way. Out of the _Romanza_ he makes a hymn.

The part played by society in bringing morality into existence cannot, according to Bentham, be emphasized too strongly. In vehement words he opposes the view that the human conscience can decide between good and evil. Nothing can be left to subjective feeling. Man is truly moral only when he receives his ethics at the hand of society and works them out with ardour.

But if society is to decide about ethics, it must first bring order into its own ethical views, and therefore, says Bentham, must learn to combine clear and definite notions [pg 078] with its presentation of the general good. That done, it must make up its mind to apply this principle with absolute consistency as a foundation for legislation and the establishment of ethical standards, excluding all considerations of a different character. A “moral arithmetic” should be constructed which allows the calculating in correct utility values of all decisions that have to be made.

Dealing in a dry, practical way with all cases of penal legislation, and of establishment of standards by the moral law, Bentham then shows that the principle of the greatest good of the greatest number is applicable in all of them, and guides us safely and accurately in questions of good and evil.

“Moral philosophy, in its general meaning, is the theory underlying the art of so directing the actions of men that there is produced the greatest possible amount of happiness.”

It is legislation that decides what moral actions the community can order to be performed, and if it is to exert an educative influence it must be humane through and through.

“But there are many actions which, though useful to the community, legislation may not command. There are even many injurious actions which it may not forbid, although moral philosophy does so. Legislation is, in a word, a circle with the same centre as moral philosophy, but its circumference is smaller.”

When law ceases to be available, there is nothing that society can do except be continually putting before the individual personally how greatly he contributes to his own welfare by furthering that of others. Bentham does not make it do this with educative guile as does Helvetius. Society appeals to his feeling for truth. It throws itself at his feet and entreats him for the sake of the general welfare to listen to the voice of reason. Thus the dry way in which Bentham writes about ethics has in it something peculiarly impressive, and explains the powerful influence which this [pg 079] eccentric member of the House which looks across the Park at Westminster has exercised all over the world through the individuals who were inspired by him.

The most influential parts of his work are those in which he intensifies the seriousness of men and sharpens their outlook by leading them to reflect not only on the immediate but also on the more distant consequences of anything done or left undone, and, further, not only on the material consequences but on the spiritual ones. It does one good to note the courage with which this fanatic for utility ventures to represent material blessings as the foundation of spiritual ones.

Bentham is one of the most powerful moralists who have ever appeared in the world, but his mistakes are as great as his insight. The latter is shown in this, that he conceives morality as a kind of enthusiasm. His mistake is that he thinks he must guarantee the rightness of this enthusiasm by making it nothing higher than a judgement of society which is taken over by the individual.

This compels us to rank Bentham with Hobbes, Locke, and Helvetius, although in other respects he stands high above them. He, like them, makes morality arise outside the individual. He, like them, in order to find his explanation of the altruistic, puts out of action the ethical personality which is in man, and, to compensate for this, raises society to an ethical personality that he may then by a transmission of energy connect individuals with this central power-station. The difference is only that with the other commonplace moralists the individual is a marionette directed by society on ethical principles, whereas in Bentham he carries out with deep conviction the movements suggested to him.

Ethical thought falls from one paradox into another. If, as in antiquity, it thinks out a system in which the activity that must be directed to the common good is not sufficiently represented, it arrives at ethics which are no longer ethics, and ends in resignation. If it assumes and starts from such an activity directed to the common good, [pg 080] it arrives at an ethic in which there is no ethical personality. It is, strange to say, unable to mark out the middle course and let an activity which is directed to the promotion of the common good spring out of the ethical personality itself.

Altruism as a natural quality. Hume, Adam Smith

The explanations of altruism as an ennobling of egoism which has a spontaneous origin through the activity of reason, or which is brought into existence through the influence of society, are obviously unsatisfying both psychologically and ethically. Utilitarianism must therefore necessarily come to admit that altruism is somehow or other given independently in human nature side by side with egoism. It is true that it always appears there as the backward twin-brother who can be reared only with the most careful nursing, and therefore the upholders of the third alternative given above appeal to the considerations used for the first two. They continually

allow the capacity for altruistic feeling to be exposed to the influence of considerations which seem calculated to let egoism discharge its waters into altruism. The two first views are taken into service as wet-nurses for the third. David Hume (1711-1776)_(_19_)_ and Adam Smith (1723-1790)_(_20_)_ must be named here.

Hume agrees with the other utilitarians in allowing that the principle of seeking to promote the common good must be accepted as the dominant principle of morality. Whether actions are good or bad is decided solely by whether they are directed towards the production of general happiness [pg 081] or not. There is nothing which is in itself ethical or unethical.

To the idea that ethics can have as their object the self-perfecting of the individual as little weight is given by Hume as by the other utilitarians. Like them, he opposes asceticism and other life-denying demands of Christian ethics, because he cannot discover in them anything profitable for the general welfare.

But what makes men decide to work together for the common good? Consistent utilitarians answer: Reflexion about what the common good means. Of this one-sidedness Hume is not guilty, because he does not find it to be in accord with psychological facts. It is not out of high-minded reflexion, he asserts, but out of direct sympathy that the emotions and actions of benevolence arise. The virtues which serve the common good have their origin in feeling. We can resolve on acts of love only because there is in us an elementary feeling for the happiness of men, and a dislike of seeing them in misery. We become moral through sympathy.

It would not have been a big step further to explain this sympathy as a form of the egoistic need of happiness, more or less through the assumption that in order to be really happy a man must see happiness all round him. But Hume does not use such roads as that. He does not aim at constructive thought but at stating facts, and it is enough for him that direct sympathy with other men be proved to be a principle inherent in human nature. We have to stop somewhere or other, he says in one place, in our search for causes. In every science there are certain general principles beyond which there is no more general principle still for us to discover.

Among the elements which are effective in developing moral feeling, Hume attributes great importance to the love of fame. This keeps us considering ourselves in the light in which we wish to appear in the eyes of others, for the effort to secure the respect of others is a potent educator in virtue. On this point he thinks like Frederick the Great, from whom comes the sentence: “The love of fame [pg 082] is innate in noble souls; you have only to arouse it and urge it on, and men who till then merely vegetated, will seem to you, when explained by this happy instinct, to be changed into demi-gods.”_(_21_)_

Adam Smith wishes to trace out the idea of sympathy in all its manifestations, and in doing so he discovers that our capacity for sympathy covers more than participation in the weal or woe of others. It brings us, he says, to a community of thought with those who are doing something. We feel ourselves directly attracted or repelled by the actions of others and the motives at the back of them. Our ethics are the product of these sympathetic experiences. We come in time to take care that an impartial third party can justify and sympathise with the mainspring and the tendency of our actions. Innate sympathy not only with the actions but also with the experience of others is thus the beneficent regulator of the behaviour of men to one another. This feeling God has implanted in human nature that it may keep men faithful to work for the common good.

How far this somewhat artificial extension of the notion of sympathy through the doctrine of the impartial third party really means a step forward beyond Hume we may leave undiscussed.

In his famous work, _An Inquiry into the Nature and Causes of the Wealth of Nations_ (1776), Adam Smith founds this prosperity purely upon the entirely free and intelligent activity of egoism. About the part to be played by ethics in economic questions he says nothing. Economic development he leaves to be determined by its own internal laws, and is confident that, if these are left a free course, the result will be favourable. Adam Smith, the moral philosopher, is also, because he is endowed with a rationalistic optimism, the founder of the _laissez-faire_ form of economic [pg 083] doctrine, that of the Manchester school, as it is called. He led industry and commerce in their struggle for liberation from the petty and injurious tutelage of authority. To-day, when economic life among all peoples is again delivered over to the most short-sighted ideas of authorities who never think in terms of economics, we can measure the greatness of his performance.

Like Adam Smith, Bentham also is an adherent of the principle of freedom in economic life. At the same time he has an ethical conception of society, and demands from it that in a spirit of progress it shall help to level out as far as possible the differences between rich and poor.

What, then, do Hume and Adam Smith mean for ethics? They introduce into the treatment of them the element of empirical psychology. They believe that through the value they give to the significance of sympathy they are giving a natural foundation to

utilitarianism, though in reality this psychology begins to correct it and to undermine its position. There hovers before the mind of utilitarianism the great conception that ethics are a result of reflexion. It thinks to make men moral by keeping their attention fixed on the deep nature of ethics and the necessity of the ends at which it aims.

This conception draws its life from the conviction that thought has been given complete control over the will. The absolute rationality of the ethical is the foundation on which it builds, and if it is not to get quite bewildered about its own nature, it cannot allow itself to recognize as presuppositions of the ethical, facts which are given it by psychology and cannot be verified independently.

With Hume and Adam Smith, who trace ethics back to something given in human nature which resembles instinct, there crops up the problem how ethics can be something natural, and at the same time something subordinate to thought, for that they are subordinate to thought has to be assumed even by the champions of this psychological utilitarianism. If they were nothing but the exercise of an instinct, they would not be capable of widening and [pg 084] deepening, nor could they be imparted to all and sundry with convincing force. Yet how is it conceivable that thought influences the sympathetic instinct? What have the two in common that the work of one can be carried further by the other?

If Hume and Adam Smith had suspected the far-reaching character of this great problem of ethics which they brought into the field of discussion, they would have had to go on and settle the extent and the depth of this sympathy which they adopted in their scheme, in order to understand how it continues to function in the domain of thought.

But they fail to notice the far-reaching character of what they lay down, and believe they have done nothing but give by means of psychology an explanation of altruism which is superior to these currents. The spirit of the time, in its wonderful capacity for holding various ideas side by side, takes possession of their view, and the popular utilitarianism now confidently appeals to it as declaring that altruism is to be conceived as a rational ennobling of egoism, as a result of the influence of society, and in addition as a manifestation of a natural instinct.

It is, really, only in appearance that the psychological conception of ethics imparts new life to utilitarianism. It is rather a consumption germ which the latter absorbs. The establishment of a natural element in ethics, when the consequences of it begin to make themselves felt, can only end in its devouring rationalist utilitarianism, as becomes evident in the nineteenth century when biological thought becomes influential in ethics. The funeral procession of rationalist utilitarianism begins to assemble with Hume and Adam Smith, though it is a long time before the coffin is taken to the cemetery.

The English ethic of self-perfecting

Against the utilitarians, who would derive from the content of the moral the essential nature of it, and the [pg 085] obligation to morality, the “Intellectualists” and the “Intuitionists” enter the lists. The empirical derivation of ethics seems to them to be an endangering of the majesty of the moral. Morality—this is the thought before their minds—is a striving after perfection, and this develops itself in us because it is implanted in us by nature. Action for the common advantage does not by any means constitute ethics; it is only a manifestation of the struggle after self-perfecting.

To this deeper and more comprehensive conception of ethics, however, the Intellectualists and Intuitionists do not give correct expression. For that they are still too much entangled in a lifeless and semi-scholastic philosophizing.

Their chief strength lies in their showing up of the weaknesses of the foundation which Hobbes and Locke give to ethics, and to these they principally devote themselves, bringing to their task a great deal that is correct about the directly and absolutely binding character of the moral law. That the meaning of the moral is not to be found merely in the useful character of the actions inspired by it but also in the self-perfecting of the agent which is effected by them, and that morality presupposes a moral personality, is emphasized by them in many happy turns of expression.

When, however, the task before them is to describe exactly in what way men carry in them the idea of the good as a force which works effectively upon their character, the Intellectualists and the Intuitionists land themselves in a psychologizing which is sometimes ingenious, but often artificial and commonplace. They occupy themselves with logical distinctions instead of investigating in a practical fashion the nature of man. Instead of really developing the problem in answer to the innovators, they work at it with data taken from an out-of-date philosophy. They hark back largely to Plato, and again they argue largely, anxiously or unconsciously, not as philosophers, but as theologians.

On individual points they diverge from each other, and [pg 086] attack each other's positions according as they would have the foundations of the ethical more intellectualist, or more sentimental and mystical, or more theological.

The majority of these anti-utilitarians belong to the Cambridge Platonizing school. We must name here Ralph Cudworth (1617-1688),_(_22_)_ Henry More (1614-1687),_(_23_)_ the Rev. Samuel Clarke (1675-1729),_(_24_)_ Bishop Richard Cumberland (1632-1718),_(_25_)_ and William Wollaston (1659-1724)._(_26_)_

According to Cudworth the truths of morality are just as evident as these of mathematics. For More the ethical is an intellectual power of the soul meant for the control of natural impulses. Cumberland finds the moral law given in the reason which has been bestowed upon man by God. Clarke, living in the thought world of Isaac Newton, sees it as the spiritual phenomenon which corresponds to the law of nature. Wollaston defines it as that which is logically right.

Pressed back to their fundamental meaning, these thinkers do nothing but amplify the statement that the ethical is ethical. They assert that the utilitarian view of ethics is pitched too low, but they do not succeed in establishing, in contrast to it, a more exalted principle in such a way that a higher and more comprehensive content of ethics can be derived from it. As to content their ethic does not really differ from that of the utilitarians. It merely lacks the great enthusiastic driving-force which shows itself in the latter. To establish a living ethic of self-perfecting is beyond the capacity of the Intellectualists and the Intuitionists.

What is the inner connexion between the struggle for self-perfecting and action for the common advantage? That [pg 087] is the weighty question of ethics which crops up in the settlement of differences between the utilitarians and their conservative opponents. At first it remains veiled, and it does not come to clear expression till we reach Kant.

* * * * *

A peculiar position in the ethical thought of the eighteenth century is held by Anthony Ashley Cooper, Earl of Shaftesbury (1671-1713)._(_27_)_ He opposes not only the utilitarians, but the Intellectualists and the Intuitionists as well, and tries to secure a mediating position between them. That the content of ethics is utilitarian he openly admits, but he derives the ethical neither from considerations of usefulness nor from the intellect; he places its origin in feeling. At the same time he emphasizes, as does Adam Smith also a few years later, its relationship to the æsthetic.

But the important thing is that he puts forward a living philosophy of nature which connects itself with ethics. He is convinced that harmony reigns in the universe and that man is meant to experience this harmony in himself. Æsthetic feeling and ethical thinking are for him forms of a growing union with the divine life, which struggles to find expression in the spiritual being of man as it does in nature.

With Shaftesbury ethics descend from a rocky mountain range into a luxuriant plain. The utilitarians know as yet nothing of a world. Their ethic is contained in considerations about the relation of the individual to society. The anti-utilitarians have some idea of a world, but not a correct one. They elaborate ethics with a formal theology and a formal philosophizing about the All, but Shaftesbury plants ethical thought in the universe of reality, which he himself contemplates through an idealising optimism, reaching thereby a direct and universal notion of the moral.

[pg 088]

A mysticism based on a philosophy of nature begins to spin its magic threads through European thought. The spirit of the Renaissance rules again, no longer, however, like a raging storm, as in Giordano Bruno, but as a gentle breeze. Shaftesbury thinks pantheistically, more pantheistically than he confesses to himself, but his is not a pantheism which throws his age into struggles about world-views, and comes into conflict with theism. It is the pantheism which rules in Hinduism and in Late Stoicism also; one which is not dangerous, and raises no question of principle, desiring only to be regarded as a vivifying of belief in God.

Shaftesbury exerts also a liberating influence on the spiritual life of his time by giving ethics a much freer attitude towards religion than anyone had ventured to do up to that time. Religion, according to him, has not to give decisions about ethics, but on the contrary must test its own claims to be true by its relation to pure ethical ideas. He even ventures to represent the Christian teaching about rewards and punishment as not consistent with pure ethical considerations. Morality, he says, is pure, only when good has been done simply because it is good.

His optimistic-ethical philosophy of nature is offered by Shaftesbury only as a sketch. He throws out his ideas without proving that they are well founded, and without feeling any necessity for thinking them out to a conclusion. He steps with an easy stride across

all problems. What a difference between his philosophy of nature and Spinoza's! Yet his meets the needs of his time. He offers what is new to it, and what inspires it: ethics bound up with a living world-view.

The belief in progress now clothes itself in a living world-view which really suits it. This is the process which, thanks to Shaftesbury, began in the first decades of the eighteenth century and went on developing till the end of it. Hence the appearance of his writings, which were immediately spread abroad through the whole of Europe, [pg 089] is the great event for the spiritual life of the eighteenth century. Voltaire, Diderot, Lessing, Condorcet, Moses Mendelssohn, Wieland, Herder, and Goethe too, are under his influence, and he dominates popular thought completely. Hardly ever has any man had so direct and so powerful an influence on the formation of the world-view of his time as the invalid whose life ended at Naples when he was only forty-two.

Direct continuators of Shaftesbury's ethic are found in Francis Hutcheson (1694-1747)_(_28_)_ and Bishop Joseph Butler (1692-1752),_(_29_)_ but they take from it just that soft indefiniteness which gives it its charm and its strength. Hutcheson, who strongly emphasizes theology's independence of ethics, the relationship of the latter to the æsthetic, and their utilitarian content, stands nearer to his teacher than does Butler, who does not go as far in his welcome of utilitarianism, and also opposes, from the Christian standpoint, the optimism of Shaftesbury's world-view.

But Shaftesbury's true successor is J. G. Herder (1744-1803). In his _Ideas on the Philosophy of Human History_ (4 vols., 1784-1791), he carries the optimistic-ethical nature-philosophy on into a corresponding philosophy of history.

[pg 090]

CHAPTER VIII

LAYING THE FOUNDATIONS OF CIVILIZATION IN THE AGE OF RATIONALISM

The Mentality and the Achievements of the Ethical Belief in Progress

THANKS to the fully worked out optimistic-ethical world-view with which the belief in progress surrounds itself in the course of the eighteenth century, these generations prove capable of thinking out the ideals of civilization and advancing towards their realization. The fact that all attempts to give ethics a foundation in reason have turned out on the whole unsatisfactory does not move them, if indeed they give the point any consideration at all. By the conviction that they have formed a rational conception of the world which gives it an optimistic-ethical meaning, they are carried on over all the inner problems of ethics. The alliance which belief-in-progress and ethics have in the course of modern times contracted with one another is sealed by means of their world-view, and now they set to work together. Rational ideals are to be realized.

The ethical and the optimistic come into power, therefore, in the world-view of the eighteenth century, although they have not yet received any real foundation. Scepticism and materialism range around the fortress like hordes of unconquered enemies, though at first without being dangerous; as a rule they have themselves absorbed no small amount of belief-in-progress and of ethical enthusiasm. Voltaire is an example of the sceptic who stands under the restraint exercised by the prevalent optimistic and ethical thought.

So far as its elements are concerned the world-view of rationalism hides itself under the optimistic-ethical monism [pg 091] of Kungtse (Confucius) and the Later Stoics, but the enthusiasm which supports it is incomparably stronger than any felt by them. The circumstances, too, amid which it appears are far more favourable, and so it becomes an elemental power throughout a whole people.

In a world-view which springs from a noble faith, but is remarkable also for the extent of its knowledge, the men of the eighteenth century begin to think out ideals of civilization and to realise them in such measure that the greatest epoch in the history of human civilization now dawns.

The great feature of the mentality of this belief in progress which is ever showing itself in works is its magnificent want of respect for all existing things, whether belonging to the past or the present. These are to it in all their various forms the imperfect, which is destined to be replaced by a perfect.

The eighteenth century is thoroughly unhistoric. In what is good as in what is bad it cuts itself loose from whatever was or is, and is confident of being able to put in its place something that is more valuable, because more ethical or more in accordance with reason. In this conviction the age feels itself so creative that it has no understanding for creations of original genius. Gothic

buildings, early painting, J. S. Bach's music, and the poetry of earlier ages, are felt by these generations as art which was produced at a time when taste had not yet been purified. Activity which follows rules in accordance with right reason will, they think, introduce a new art which will be superior in every respect to any that has preceded it. Full of this self-confidence, a mediocre musician like Zelter in Berlin works over the scores of Bach's Cantatas. Full of this self-confidence, honourable poetasters re-write the texts of the wonderful old German chorales and replace the originals in the hymn books with their own wretched productions.

That they so naïvely push forward right into the sphere [pg 092] of art the boundaries of the creative faculties with which nature endowed them is a mistake made by these men for which they have often been laughed at. But mockery cannot do them much harm. In those departments of life in which the important matter is the shaping of things according to ideals given by reason—and work done upon such things means for the establishment of civilization very much more than any work spent in the promotion of art—they are as creative as any generation ever has been, and as scarcely any will be in the future. They are frightened by nothing which has to be undertaken in this sphere, and in every department they make the most astonishing advance.

They venture also to deal with religion. That religion should be split up into various antagonistic confessional bodies is to them an offence against reasonable reflexion. Only a relative, not any absolute authority, they maintain, can be allowed to the belief which is handed down in historical formulas. Finding expression in so many and such varied forms it can, of course, be nothing but a more or less imperfect embodiment of the ethical religion taught by reason, which must be equally intelligible to all men. The right thing is, therefore, to strive after the religion of reason, and to accept as true only such parts of the various confessions as are in harmony with it.

The churches, naturally, put themselves on the defensive against this spirit, but against the strong general convictions of the age they are unable in the long run to hold out. Protestantism succumbs first, because the elements already within it allow such considerations to find easy access. It carries within itself impulses to rationalism, inherited from Humanism, from Huldreich Zwingli (1484-1531) and from the Italians Lælius (1525-1562) and Faustus Socinus (1539-1604), and these impulses, hitherto suppressed, now find themselves set free._(_30_)_

[pg 093]

Catholicism shows itself more capable of resistance. Nothing in its past makes it inclined to enlist under the banner of the spirit of the age: its strong organization serves as a protection against this. Yet it, too, has to yield considerably, and to allow its doctrines to pass, so far as may be, for a symbolic expression of the religion of reason.

While utilitarian ethics are on the whole the product of the English spirit, the whole of Europe takes part in the expounding of the religion of reason. Herbert of Cherbury (1582-1648), John Toland (1669-1722), Anthony Collins (1676-1729), Matthew Tindal (1655-1733), David Hume (1711-1776), Pierre Bayle (1647-1706), Jean-Jacques Rousseau (1712-1778), Voltaire (1694-1778), Denis Diderot (1713-1784), Hermann Samuel Reimarus (1694-1768), Gottfried Wilhelm Leibniz (1646-1716), Christian Wolff (1679-1754), Gotthold Ephraim Lessing (1729-1781), Moses Mendelssohn (1729-1786), and a host of others, whether standing nearer to or further from the Church, and whether or not going further than others in systematic criticism, all bring stones for the erection of the great building in which the piety of illuminated mankind is to live._(_31_)_ The researches in the history of religion made by the Germans, like Johann Salomo Semler (1725-1791), Johann David Michaelis (1717-1791), and Johann August Ernesti (1707-1781), provide scientific data which throw light upon the division between eternal truths and the time-conditioned convictions of religion.

The creed of the religion of reason is simply the optimistic-ethical world-view reproduced in a Christian phraseology, that is in one preserving within it the Christian theism, and the belief in immortality. An all-wise and wholly benevolent Creator has produced the world, and he upholds it in [pg 094] corresponding fashion. Men are endowed with free will, and discover in their reason and their heart the moral law which is meant to lead individuals and mankind to perfection, and to accomplish in the world God's highest purposes. Every man has within him an indestructible soul, which feels his moral life as the highest happiness, and after death enters a state of a pure, spiritual existence.

This belief in God, in virtue, and in immortality was held to have been taught in its purest form in previous ages in the teaching of Jesus, but it was acknowledged that elements of the same beliefs were to be found in all the higher religions._(_32_)_

If the eighteenth century attained to an optimistic-ethical world-view which preached itself so confidently and was so widely accepted, the reason is that it was able to re-interpret Christianity—which had by that time got rid of the world- and life-denial that

was originally inherent in it—in that sense. Jesus was to it a teacher who even in his own age and then through all the intervening centuries had been misunderstood, and was now first rightly accepted as a revealer of the religion of reason. Let anyone read a rationalistic Life of Jesus, such as those of Franz Volkmar Reinhard (1753-1812) or Karl Heinrich Venturini (1768-1849)._(_33_)_ They hold Jesus up to admiration as the champion of enlightenment and of blessings for the common people. This transformation of the historical picture is made easier for them by the fact that the chief component element of the Gospel narrative is ethical teaching, while the late-Jewish pessimistic world-view which it presupposes is hardly more than hinted at.

[pg 095]

As an immediate result of the wiping out of confessional differences the middle of the eighteenth century sees the beginning of a period of tolerance in place of the persecution of all rejecters of orthodoxy which had been common till then. The last serious act of confessional intolerance was expulsion of all evangelicals from the Salzburg district by the Archbishop of that town, Count von Firmian, in the years 1731 and 1732.

About the middle of the century there begins also the movement of opposition to the Jesuits, who were recognized as the enemies of tolerance, and this led to the suppression of the order in 1773 by Pope Clement XIV._(_34_)_

But the religion of reason fought superstition as well as intolerance. In 1704 the philosopher and jurist of Halle, Christian Thomasius (1655-1728), published his essays condemning trial for witchcraft,_(_35_)_ and about the middle of the century the law courts in most of the States of Europe refused to concern themselves any longer with the crime of magic. The last death sentence on a witch was passed in 1782 at Glarus, in Switzerland.

About the end of the century it became good form to detest anything which had even a remote connexion with superstitious convictions.

Again, the will-to-progress of the eighteenth century deals with nationalist prejudices in the same way as it deals with religious ones. Above and beyond individual nations it points to mankind as the great object towards which ideals are to be directed. Educated people accustom themselves to see in the State not so much an organ of national feeling as a mere organization for legal and economic purposes. Cabinets may carry on war with each other, but in the thought of the common people there grows up a recognition of the brotherhood of nations.

In the sphere of law, too, the will-to-progress acquires [pg 096] strength. The ideas of Hugo Grotius get accepted. The law of reason is exalted in the convictions of the men of the eighteenth century to a position above all traditional maxims of jurisprudence. It alone is allowed to have permanent authority, and legal decisions have to be in harmony with it. Fundamental principles of law, but principles equally indisputable everywhere, have to be deduced from human nature. To protect these and to ensure to every human being a human value with an inviolable measure of freedom of which he can never be robbed, is the first task of the State. The proclamation of “the Rights of Man” by the States of North America, and the French Revolution, do no more than give recognition and sanction to what, in the convictions of the time, had already been won.

The first State in which torture was abolished was Prussia, and this was secured by an administrative order of Frederick the Great’s in 1740. In France a certain amount of torture was practised down to the Revolution— and somewhat later, for the thumb-screw was used under the Directory during the examination which the royalist conspirators had to undergo._(_36_)_

Side by side with the fight against absence of law and the existence of inhuman laws, go efforts to adapt law to circumstances. Bentham raises his voice against laws which tolerate usury, against senseless customs duties, and against inhuman methods of colonization.

There dawns an age in which the purposive and the moral are the ruling authorities. Officialdom acquires during these generations familiarity with the notions of duty and honour, which later become natural to it. Far-reaching beneficial reforms are introduced into administration without any outcry.

The education of mankind in citizenship makes splendid progress. The general good becomes the criterion of [pg 097] excellence both for the commands of rulers and the obedience of their subjects, while at the same time a beginning is made of securing that everyone shall be educated in a manner corresponding to his human dignity and the needs of his personal welfare. The war against ignorance is begun.

The way is prepared, too, for a more rational method of living. Houses are built so as to be more comfortable, and the land is better cultivated. Even the pulpit uses its influence to promote improvements of this kind. The theory that reason has been given to man to be used consistently and in every department of life plays at this time an important and beneficent part in the preaching of the Gospel, even if the way in which this is done often makes queer demands on our belief. Sermons, for example, often treated incidentally of the best methods of manuring, irrigating, and draining the fields. That Jenner's discovery of vaccination was so readily adopted in many districts was due to the enlightenment which was spread abroad by the clergy.

Characteristic of the age of rationalism are the private societies formed to promote the moral and utilitarian progress of mankind. In 1717 members of the higher ranks of society in London reorganize as "The Order of Freemasons" the brotherhood which in earlier times had been built up by the union in a single body of the members of the mediæval building-lodges, but was now in a state of decay, and to this new organization was assigned the duty of labouring to build up a new humanity. About the middle of the century this order had spread all over Europe, and reached the zenith of its success. Princes, officials, and intellectuals alike joined it in great numbers, and were inspired by it to the achievement of a huge amount of reform.

Similar aims were pursued by the "Order of the Illuminate" (or enlightened) which was founded in Bavaria in 1776, but was suppressed in 1784 by the reactionary Bavarian Government, which was still under the influence [pg 098] of the Jesuits. It is said to have been the intellectual counterpart of the Jesuit order, on the model of whose organization it was formed.

That private societies aiming at the rational and moral perfecting of mankind should work effectively seemed to the men of the eighteenth century so much a matter of course that they assumed them to have existed in earlier times. In a series of rationalist descriptions of the life of Jesus it is assumed that the sect of the Essenes, near the Dead Sea, of whom we learn from Josephus, the Jewish writer of the first century A.D., was such an order, and that it was in touch with similar brotherhoods in Egypt and India. Jesus, it is said, was trained by them, and then helped by them to carry through the _rôle_ of the Messiah, in order that with the authority given by a holy yet popular personality he might work to spread true illumination. The famous _Life of Jesus_ by Karl Venturini carries this assumption out in complete detail. According to him, the miracles of Jesus were staged by brothers of this secret association.

Be that as it may, the fact that the will-to-progress of the eighteenth century created for itself in these private societies organizations which spread throughout Europe, contributed much to its ability to influence the age.

It must be admitted indeed that the men of the rationalistic period were smaller than their achievements. True, they all possessed personality, but it did not reach very deep. It was produced by the enthusiasm which they found in the mentality of the time and which they shared with all their contemporaries. The individual imbibed personality through the taking over of a ready-made world-view, which gave him firm standing-ground together with ideals. His own contribution was really nothing more than the capacity for enthusiasm. That is why the men of this age are so remarkably like one another. They all graze side by side in the same nourishing pasture land.

Nevertheless, the ideas of the purposive and the ethical [pg 099] have never exercised so much influence over reality as they did among these men of shallow optimism and sensitive morale. No book has been written yet which fully describes their achievements, doing justice to their origin, their character, their number, and their significance. We can then only really comprehend what they accomplished when we recognize the tragic fact that the most valuable part of it is lost to us, while we do not feel in ourselves any ability to reproduce it. They were masters of the facts of life to an extent which we are to-day quite unable to realize.

Only a world-view which accomplishes all that rationalism did has a right to condemn rationalism. The greatness of that philosophy is that its hands are blistered.

Obstacles to the reform movement. The French Revolution

The great work of reform is never completed, partly because external circumstances arise which check it, but also because the world-view of rationalism becomes convulsed from within. In its confidence in the enlightening power of all that is in accordance with reason the will-to-progress was inclined to underestimate the resisting power of the traditional, and to wish to carry through reforms where minds had not been sufficiently prepared for their reception. On these unsuccessful advances followed reaction which permanently injured the work. This was the case in south-eastern Europe. Joseph II. of Austria, who was emperor from 1764 to 1790, is the type of the reforming prince. He discontinued the use of torture, opposed the infliction of the death penalty, abolished

serfdom, gave the Jews full civic rights, introduced a new method of legislation and a new system of legal administration, took away all class privileges, contended for the equality of all before the law, protected the oppressed, founded schools and hospitals, guaranteed the freedom of the Press and freedom of domicile, abolished all State monopolies, and promoted the development of agriculture and industry.

[pg 100]

But he is a ruler in the wrong place. He decrees these reforms and then similar shocks, one after another, in countries which, being in spiritual things still wholly under the dominion of the Catholic Church of that time, are not prepared for them, and moreover in other things as well display a specially backward attitude, because they belong to the zone in which the Europe of that day passed over into Asia. The Emperor is therefore unable to count upon either any willingness to make sacrifices in the classes which are to give up their privileges, or upon any understanding of his ideas in the common people. In his attempts to organize the monarchy as a unity and in an effective way for practical purposes, he comes into conflict with the nationalities themselves of which it is composed. The reduction in the number of the religious houses, which he undertakes out of economic considerations, with the introduction of the freedom of the Press and of a system of State education, bring on him the hostility of the Church. Finally, because he is a ruler in the wrong place, this noble reforming emperor dies of a broken heart, while Europe, because the will-to-progress in Austria can accomplish nothing even at the time of its greatest strength, owing to unfavourable circumstances, is condemned to a period of the deepest misery over the problems of that huge State, which have in this way been rendered insoluble, and over the portion of Asia beyond it along the southern Danube.

In France, too, the wrong men are in control. There the spread of the new ideas prepares the way splendidly for reform, but the reforms are not undertaken, because its rulers cannot understand the signs of the times, and allow the State to collapse in ruin. Consequently the reform movement has to take the road of violence, whereby it slips away from the guidance of the educated, and falls into the hands of the mob, from which it is taken by the powerful genius of Napoleon. Native of an island in which the Europe of that day passed over into Africa, and lacking all [pg 101] deeper education, he is uninfluenced by the valuable convictions of his time. Guided solely by the force of his own personality, he decides what is to happen in Europe, and hurls it into wars through which it sinks into misery. Thus from East and from West alike disaster overtakes the work of the will-to-progress.

The French Revolution is a snowstorm falling upon trees in blossom. A transformation which promises great things is in progress, but everywhere softly and slowly. Extraordinarily valuable results are being prepared in the thoughts of men. Provided that circumstances remain even tolerably near the normal, there stands before humanity in Europe an extraordinarily desirable development. But in place of that there sets in a chaotic period of history in which the will-to-progress has to cease more or less completely from its work, and becomes a bewildered spectator. The first stage of the advance of reforming thought, thought bent with full consciousness of its aims on securing the practical and the ethical, comes to a complete stop.

An experience for which it was in no wise prepared now falls to the lot of the will-to-progress. Up to this time it had always been a more or less obsolescent reality with which it had had to come to terms. In the French Revolution, however, and in the following period, it becomes familiar with a reality which has at its disposal elemental forces. Up to this time the only factor to be reckoned with had been the force of originality exercised by rational thought. In Napoleon it has to learn to recognize as power a personality with creative genius of its own.

By his reorganization of France, a magnificent work but concerned only with the technical matters of administration, Napoleon creates a new State. His work, too, has had the way prepared for it by the labour of rationalism, so far as this upset the equilibrium of the old and made current the idea of something new but necessary. But the new State which now comes into existence is not the State [pg 102] which is ethical and in harmony with reason, but merely the State which works well. Its achievements compel our admiration. In the nursery garden which the will-to-progress was laying out in order to plant it with noble flowers an individual ploughs for himself a piece of ordinary arable land which at once produces an excellent crop. With the elemental creative forces of reality revealing their power in so imposing a fashion, the noble but unoriginal spirit of the age, with all its higher aims, finds itself in a state of instability from which it never completely recovers. Hegel, who saw Napoleon ride past after the Battle of Jena, tells us that he then saw the World-spirit on horseback. In these words we can hear all the confused spiritual experience of that time expressing itself.

The undermining of the rationalistic world-view

There now sets in a development which works against the spirit of the times, and the hitherto unopposed authority of the rational ideal is undermined. Forces in reality which are not guided by it, obtain recognition.

While the will-to-progress remains an amazed spectator of events, respect for what is historical recovers itself, though it seemed to have been banished for ever. In religion, in art, and in law, men begin, though at first only quite shyly, to look again with other eyes on the traditional. It is no longer reckoned as merely something which is to be replaced, but men venture to admit to themselves that it conceals within itself original values. The forces of reality, which had been taken by surprise, now begin everywhere to act on the defensive, and a guerilla warfare develops against the will-to-progress.

The various religious bodies revoke the abdications which they had made before the religion of reason. The law which has grown up in the course of time begins to set itself in opposition to the law laid down by reason. In the atmosphere of passion produced by the Napoleonic wars, [pg 103] national thought takes on a new character, directing on itself, and beginning to absorb, the universal enthusiasm for ideals. The struggles carried on no longer by chancelleries but by whole nations are fatal to the ideals of cosmopolitanism and national brotherhood, and by this awakening of national thought a whole series of political problems affecting the whole of Europe are rendered insoluble. Just as the organization of Austria as a unified modern State has now become impossible, so also has the civilizing of Russia, and the destiny of Europe, viz. to be shipwrecked over these territories which are in it but not of it, begins to reveal itself.

At the close of the Napoleonic era the whole of Europe is in a condition of misery. Far-seeing ideas of reform can be neither thought out nor worked out; only extemporized palliative measures suit the time. The will-to-progress is therefore unable to recover its former vigour.

It is fatally affected, too, by the fact that everybody with any capacity for independent thought feels himself attracted by this new valuation of things and facts, and thereby drawn on to irritation at the one-sided, doctrinaire character of the rationalist way of looking at life.

Nevertheless, the position of the will-to-progress is far from being a critical one. The first attacks are made by Romanticism and the feeling for reality, but are mere outpost-skirmishes, and for a long time yet the will-to-progress remains master of the field. Bentham remains still the great authority. Alexander II. of Russia, Tsar from 1801 to 1825, instructs the legislative commission which he sets up to obtain on all doubtful points the opinion of the great Englishman. Madame de Staël expresses the opinion that the fateful period she has lived through will one day be called by posterity not the Napoleonic age but the Benthamite._(_37_)_

The noblest men of the period still live in the unshaken [pg 104] conviction that nothing can delay the speedy and conclusive victory of the purposive and moral. The philosophically minded mathematician and astronomer, the Marquis Marie Jean de Condorcet (1743-1794), though put by the Jacobins upon the list of the proscribed, writes, while living in concealment in Paris in a dismal room in the Rue des Fossoyeurs, his _Historical Sketch of the Progress of the Human Spirit_._(_38_)_ Then, having been betrayed, he wanders about the Clamart quarries, is recognized by the labourers, in spite of his disguise, as an aristocrat, and while confined in the prison of Bourg la Reine, puts an end to his life by poison. The document in which he gave his exposition of the ethical belief in progress concludes with a forward glance at the time, now soon to appear, when reason, having attained a position of permanent sovereignty, will put every human being in possession of the rights which belong to man as man, and will establish purposive and ethical relations in every department of life.

There is one thing, it must be admitted, which Condorcet and those who share his views overlook. Their belief that the final result will be good might be considered justifiable if the will-to-progress had been endangered only through unfavourable outward circumstances, the revival, that is, of the higher estimation of reality, and the romantic idealizing of the past. But it is threatened far more seriously by something else than it is by them. The assurance displayed by rationalism rests on the fact that it regards the optimistic-ethical world-view as something proved to be correct. But it is not that. It rests like the world-views of Confucius and the Later Stoics on a naïve interpretation of the world. All deeper thought, therefore, even if it is not directed against rationalism, or even if it aims at strengthening its position, must in the long run have a damaging effect upon it. Hence Kant and Spinoza mean doom to it. Kant undermines it by his attempt to [pg 105] provide a deeper foundation for the essence of the ethical. Spinoza, the thinker of the seventeenth century, brings it to confusion when his nature-philosophy begins, a hundred years after his death, to occupy people’s attention.

It is about the beginning of the new century, the nineteenth, just when the pressure exerted by material and spiritual circumstances alike begins to make itself felt, that the optimistic-ethical world-view begins to suspect the existence of the serious problems which

are cropping up within it.

[pg 106]

CHAPTER IX

THE OPTIMISTIC-ETHICAL WORLD-VIEW IN KANT

Kant's ethics, deepened, but lacking content

SO far as the general tendency of his thought goes Immanuel Kant (1724-1804) lives entirely in the optimistic-ethical world-view of rationalism._(_39_)_ He has, however, a feeling that its foundations are not deep and firm enough, and he regards it as his task to put them on ground which is in every respect more secure. For this purpose a deeper ethic, and a less naïve positiveness in assertions about world-view which touch upon the supra-sensible, seem to him desirable.

Like the English intellectualists and intuitionists, Kant is offended by the idea that the ethic in which the modern age finds satisfaction and its impulse to activity is rooted merely in considerations of the universal advantage of morally good actions. Like them, he feels that it is something more than this, and that in the ultimate analysis it has its origin in the compulsion which men experience to strive for self-perfecting. But while his predecessors stick fast in the matter provided by semi-scholastic philosophy and theology, he attacks the problem along the lines of pure ethical thought. It follows for him that the fundamental origin and the exalted character of the moral can be preserved only if we always consciously make it an end in itself, and never merely a means to an end. Even if moral conduct prove itself to be always advantageous and practical, our motive to it must nevertheless always be a [pg 107] purely inward compulsion. The utilitarian ethic must abdicate before that of immediate and sovereign duty. That is the meaning of the doctrine of the categorical imperative.

The English anti-utilitarians had in common with the utilitarians the thought that the moral law was related in its essence to empirical natural law. Kant, however, asserts that it has nothing to do with the order of nature, and has its origin in supra-natural impulses. He is the first since Plato to feel, like him, that the ethical is the mysterious fact within us. In powerful language he proves in the _Critique of the Practical Reason_ that ethics are a volition which raises us above ourselves, makes us free from the natural order of the world, and attaches us to a higher world-order. That is his great discovery.

In the development of it, however, he is not happy. Whoever asserts the absoluteness of moral duty, must also give the moral an absolute and completely universal content. He must specify a principle of conduct which shows itself as absolutely binding, and as lying at the foundations of the most varied ethical duties. If he does not succeed in doing this, his work is only a fragment.

When Plato announces that ethics are something supra-natural and puzzling, his world-view provides him with a basic principle of the ethical which corresponds to these qualities, and also has a definite content. He is in a position to define ethics as a process of becoming pure and free from the world of sense. This, his own special ethic, he develops in the passages where he is consistent with himself. Then, when he cannot complete his argument without an active ethic, he has recourse to the popular theory of virtue.

Kant, however, as a child of the modern spirit, cannot let world- and life-denial rank as an ethic. Therefore, since he can go only a part of the way with Plato, he sees himself faced with the confusing task of letting a purposive, activist ethic which is directed on the empirical world originate in impulses which are not determined by any adaptation to the empirical.

[pg 108]

He can find no solution of the problem thus set. In the form which he gives it it is in fact insoluble. But he never even realises that he has arrived at the problem of finding a basic principle of the moral which is a necessity of thought. He is content with formally characterizing ethical duty as absolutely binding. That duty, unless a real content is at once given to it, remains an empty concept, he is unwilling to admit. For the exalted character of his basic principle of the moral he pays the price of having it devoid of all content.

Beginnings of an attempt to establish a basic moral principle which has a content are to be found in his treatise, _Prolegomena to a Metaphysic of Morals_ (1785), and again later in _A Metaphysic of Morals_ (1797). In the 1785 volume he arrives at the dictum: "Act in such a way that you use every human being both in your own person and in everyone else's always as an end, never merely as a means." But instead of seeing how far the totality of ethical duties can be developed out of this principle, he prefers in the 1797 treatise to set before ethics two ends to be aimed at, viz. the perfecting of oneself and the happiness of others, and to enlarge upon

the virtues which promote them.

In his investigation of the ethic which aims at personal perfecting, he drives his gallery with sure instinct towards the recognition that all virtues which contribute thereto must be conceived of as manifestations of sincerity and of reverence for one's own spiritual being. He does not, however, go the length of comprehending these two as a unity, just as little does he concern himself to make clear the inner connexion between self-perfecting and effort directed to the common good, and in that way to dig down to the roots of the ethical as such.

How far Kant is from understanding the problem of finding a basic moral principle which has a definite content can be seen from the fact that he never gets beyond an utterly narrow conception of the ethical. He persists obstinately in drawing the boundary of his ethic as close [pg 109] as possible, making it concerned with no duties beyond those of man to man. The relation of man to non-human existences he does not draw within it. It is only indirectly that he includes in it the prohibition of cruelty to animals, putting this among the duties of man to himself. By inhuman treatment of animals, he says, sympathy with their sufferings is blunted in us, and thereby "comes a weakening of a natural disposition which is very helpful to our morality in relation to other men, and it gradually dies out."

Again as to the vandalism of the destruction of what is beautiful, in the form, that is, of natural objects which are viewed as entirely without feeling, this is said to be unethical only because it violates the duty of man to himself by undermining the desire—itself a support to morality—of having something to love without regard to utility.

If the sphere of the ethical is limited to the relations of man to man, then all attempts to reach a basic principle of the moral with an absolutely binding content are rendered hopeless beforehand. The absolute demands the universal. If there really is a basic principle for the moral, it must be concerned in some way or other with the relations between man and life as such in all its manifestations.

Kant, then, does not essay the task of developing an ethic which corresponds to his deepened conception of the ethical. On the whole he does nothing more than put the current utilitarian ethic under the Protectorate of the Categorical Imperative. Behind a magnificent façade he constructs a block of tenements.

His influence on the ethics of his time is twofold. He furthers it by challenging it to profounder reflection on the nature of the ethical and the ethical destiny of man. At the same time he is a danger to it in that he robs it of its simplicity. The strength of the ethic of the age of reason lies in its naïve utilitarian enthusiasm. It directly enlists men in its service by offering them good aims and objects. Kant makes it insecure by bringing this directness in question and calling for an ethic which is derived from much less elementary considerations. Depth is gained at [pg 110] the cost of vitality, because he fails to establish at the same time a basic moral principle with a content, a principle which compels acceptance from deep and yet elementary considerations.

Several times Kant actually makes it his object to block the natural sources of morality. He will not, for example, allow direct sympathy to be regarded as ethical. The inner feeling for the suffering of another as if it were one's own is not to count as duty in the real sense of the word, but only as a weakness by which the evil in the world is doubled. All help to others must have its source in a reasoned consideration of the duty of contributing to the happiness of others.

By taking from ethics their simplicity and directness, Kant also loosens the connexion which they and the belief in progress had formed with one another, and through which the two together had proved so productive of good. The disastrous separation between them which later on, in the course of the nineteenth century, became complete, was partly due to him.

In consequence of his wishing to drive out the naïve rationalistic conception of the ethical in favour of a deepened one without at the same time being in a position to establish a basic principle of it which has been correspondingly deepened, has a definite content of its own, and is directly convincing, Kant brings the ethics of his time into danger. He labours at the provision of new foundations without remembering that the house will develop cracks, if it is not propped up sufficiently.

Kant's attempt to reach an ethical world-view

Kant passes by the problem of finding a basic principle of the moral with a definite content, because, while attempting to deepen the concept of the ethical, he pursues an object which lies outside ethics. He wishes to bring ethical idealism into connexion with an idealistic representation of the world which has its source in a theory of knowledge. But [pg 111] from that source he hopes there will come an ethical world-view able to satisfy critical thought.

Why has Kant with a rigorism which intentionally depreciates ordinary moral experience ventured forward to the discovery that the moral law has nothing to do with the natural world-order, but is something super-sensible? Because he refuses, similarly, to let the sensible world which is experienced by us in space and time be accepted as anything more than a manifestation of something nonsensible which makes up true reality. The concept of a moral which contains none but inward and spiritual duties is for him the expanding ladder which he draws out so as to reach by means of it the region of Being in itself. He has no feeling of dizziness when in company with ethics, he mounts above all empirical experience and all empirical aims and objects. He is determined to go right up with her, and she can never be sufficiently _a priori_ for him, because he sets up another ladder of the same length, that of epistemological idealism, and tries to lean one against the other, so that they may give each other mutual support.

How does it come about that the theoretical assumption that the world of sensible phenomena has a non-sensible world of Being lying behind it, has any importance for world-view? Because within the notion of absolute duty which man experiences at work within himself there lies a fact of the world-order of that same non-sensible world. Hence arises the possibility, so Kant thinks, of raising to certainty by means of ethics those great elements in the non-sensible world which are of value for the optimistic-ethical world-view, viz. the ideas of God, of the ethical freedom of the will, and of immortality, which otherwise would always remain merely problematical.

So far as rationalism affirms unhesitatingly from the standpoint of theoretical knowledge the ideas of God, of the ethical freedom of the will (_i.e._, of virtue), and of immortality, which make up its optimistic-ethical world-view, it builds upon a foundation which cannot bear the weight of critical thought. Kant wishes, therefore, to erect the [pg 112] optimistic-ethical world-view as a lake-dwelling upon piles rammed into place by ethics. These three ideas are to be able to claim real existence for themselves as necessary postulates of the ethical consciousness.

This plan, however, of thus securing the position of the optimistic-ethical world-view cannot be carried out. It is only the idea of the ethical freedom of the will that can be made a postulate of the moral consciousness. To establish the ideas of God and immortality as equally “postulates,” Kant has to abandon all honourable logic and argue with bold and ever bolder sophisms.

There is no way of uniting epistemological and ethical idealism, however enticing the undertaking looks at first sight. When they are set side by side, the happenings which take place according to a law of causation subordinate to freedom, and become conscious in man through the moral law, become identified with the happenings which are universal in the world of things in themselves. There ensues a disastrous confusion of the ethical with the intellectual. If the sensible world is only a manifestation of an immaterial world, then all the happenings which come about in the space and time sphere of causation produced by necessity are only parallel appearances of the events which are brought about in the intellectual sphere of causation produced by freedom. All happenings, therefore, human activity just as much as natural happening, are, according to the point of view, at once intellectual and free, and at once natural and necessary. If ethical activity produced by freedom is represented as analogous with the results of epistemological idealism, then either everything that happens in the world, conceived as intellectual happening, is ethical, or there is no such thing as an ethical happening. Because it has chosen to put side by side these two things, human activity and natural happening, Kant’s way of looking at the question has to renounce all ability to maintain the difference between them. But the very life of ethics depends on this difference being there and effective.

[pg 113]

Epistemological idealism is a dangerous companion for the ethical. The world-order of immaterial happening has a supra-ethical character. From the setting side by side of ethical and epistemological idealism there can never result an ethical world-view: it will always be a supra-ethical one.

From epistemological idealism, therefore, ethics have nothing to expect, but everything to fear. By its depreciation of the reality of the empirical world the ethical world-view is not helped: it is injured.

Ethics have materialist instincts. They want to concern themselves with empirical happenings and transform the circumstances of the empirical world. But if that world is only “appearance,” derived from an intellectual world which functions within it or behind it, ethics have nothing on which to act. To wish to influence a self-determined play of appearances has no sense. Ethics can therefore allow validity to the view that the empirical world is mere appearance only with the limitation that activity exerted upon the appearance does at the same time influence the reality lying behind it. But thereby they come into conflict with all epistemological idealism.

Kant is defeated by the same fate which rules in Stoic, Indian, and Chinese monism alike. As soon as thought tries in any way to comprehend ethics in connexion with the world-process, it falls at once, whether it is conscious of it or not, into the supra-ethical manner of regarding it. Fully to shape ethics to an ethical world-view means letting them come to terms with nature-philosophy. Ethics are thereupon, as a matter of fact, devoured in one way or another by that philosophy, even if they are in word saved from that fate. The coupling of ethical idealism with epistemological is only bringing ethics and nature-philosophy into relation with one another in a roundabout way by which it is hoped to outwit the logic of facts. But this logic cannot be outwitted. The tragical result lies in the identification which has been made of the ethical with the intellectual.

[pg 114]

The ethical is not something irrational which becomes explicable when we betake ourselves from the world of appearance to the region of immaterial Being that lies behind it. Its intellectual character is of a peculiar kind, and rests upon the fact that the world-process, as such, comes in man into contradiction with itself. It follows that the ethical will and ethical freedom of the will are not explicable by any theory of knowledge, and cannot, moreover, serve as a support to any such theory.

As a result of conceiving the moral law and empirical obedience to natural law as in absolute opposition to each other, Kant finds himself on the road which leads to a dualistic world-view. Afterwards, however, in order to satisfy the claims of the unitary and optimistic world-view which the spirit of the age prescribes to him, he manages with the stratagems which are provided for him by the combination of ethical and epistemological idealism, to work himself back on to the road which leads to the monistic point of view.

Kant is great as an ethical thinker, great too with his theory of knowledge, but as shaper of a world-view he is not in the first rank. By his deepened conception of the nature of the ethical, a conception which lands him in dualistic thought, the problem of the optimistic-ethical world-view is unfolded in an entirely new way. Difficulties reveal themselves which till then no one could have imagined to exist. But he does not deal with them. He is blinded by his ambition to be the Copernicus of the optimistic-ethical world-view, believing that he can show the difficulties inherent in that view to be misunderstandings which explain themselves away as soon as, by means of his epistemological idealism, actual circumstances and relations take the place of these which are apparent but inexplicable. In reality he does nothing but replace the naïve optimistic-ethical interpretation of the world which was the basis of action for the rationalists by an artfully contrived one.

He does not take the trouble to ask in what the optimistic [pg 115] ethical world-view consists, to what final items of knowledge and demands it leads, and how far these are confirmed by experience of the moral law. He takes it over without examination in the formula: “God, Freedom (or Virtue), and Immortality,” which was supplied to it by rationalism, and wishes to raise it in this naïve form to a certainty.

There is thus in Kant’s philosophy the most terrible want of thought interwoven with the deepest thinking. New truths, weighty in their novelty, make their appearance in it. But they get only half-way on their journey. The absoluteness of ethical duty is grasped, but its content is not investigated. Experience of the ethical is recognized as the great secret by means of which we comprehend ourselves as “other than the world”; but the dualistic thinking which goes with it is not worked out any further. That the final items of our knowledge of our world-view are assertions of the ethical will is admitted, but the consequences of this supremacy of the will over knowledge are not thought out to a conclusion.

Kant stimulates powerfully the men of his time, but is unable to make secure for them the optimistic-ethical world-view in which they have lived. His mission is, although both he and they are content to deceive themselves in the matter, to deepen it, and ... to let it become less secure than before.

[pg 116]

CHAPTER X

NATURE-PHILOSOPHY AND WORLD-VIEW IN SPINOZA AND LEIBNIZ

Spinoza’s attempt to reach an optimistic-ethical nature-philosophy

JUST when Kant is beginning to influence men’s minds, the entirely different ideas of a thinker who had now been dead for a century, Baruch Spinoza (1632-1677),_(_40_)_ begin to interest those who are searching for a world-view. The _Critique of Pure

Reason_ appears in 1781. In 1785 F. H. Jacobi in his letters addressed to Moses Mendelssohn, _Concerning the Teaching of Spinoza_, draws attention once more to the philosopher whom hitherto everyone had attacked without making any effort to understand him.

Spinoza desires to obtain an ethic from a real nature-philosophy. He makes no attempt to give an optimistic-ethical interpretation of the universe, or to refashion it with any theory of knowledge. He accepts it just as it is in every respect. His philosophy is therefore elementary nature-philosophy, but his method of expounding it is by no means elementary. Acquiescing in the way Descartes puts the problem and the language he uses, he makes his own thought about the universe proceed “in geometrical fashion” in a series of axioms, definitions, precepts, and proofs. Nature-philosophy is embodied in his philosophizing in a magnificent way, but it is as stiff as an ice-bound landscape.

His chief work—published after his death, because he could not venture to publish it himself—he entitles _Ethics_. The [pg 117] title is confusing, because the nature-philosophy in it is developed almost as completely as the ethics. It is only when the reader has shaken himself free of all naïve conceptions in his thought about the universe that he can be permitted, according to Spinoza, to begin upon ethics. The fact that ethics too are broken up into precepts which are given as proved is very prejudicial to their exposition.

In his attempt to found ethics upon nature-philosophy, Spinoza proceeds as follows. Everything that exists, he says, is given in that infinite Being, which may be called either God or Nature. For us, and to us, it presents itself in two forms: as thought (spirit) and as corporeity (matter). Within this divine nature everything, human activity included, is determined by necessity. There is no such thing as doing, there are only happenings. The meaning of human life, therefore, cannot consist in action, but only in coming to an ever clearer understanding of man’s relation to the universe. Man becomes happy when besides belonging to the universe naturally, he also surrenders himself to it consciously and willingly, and loses himself spiritually within it.

Spinoza demands therefore a higher experience of life. With the Stoics and the thinkers of India and China, he belongs to the great family of the monistic and pantheistic nature-philosophers. Like them, he conceives of God merely as the sum-total of nature, and accepts as valid only the notion of God which makes him in this way an independent unity. The attempts, made in the interests of the ethical world-view, to allow God to be at the same time an ethical personality standing outside the universe, are to him an offence against thought. Their only object is, of course, to obtain with the help of a confessed or unconfessed dualism a starting-point for an optimistic-ethical world-view. They are striving to reach along naïve-religious by-roads the goal for which the rationalistic optimistic-ethical interpretation of the universe is making along the direct, but not less naïve, main-road.

[pg 118]

The tragic result of monistic thinking in the Stoic, the Indian, and the Chinese philosophies is that nature-philosophy, when consistent, arrives only at resignation, not at ethics. Has Spinoza escaped this fate?

Like Lao-tse, Chwang-tse, Lie-tse, and the Chinese thinkers as a body, Spinoza champions an optimistic monism without suspecting that under a far-away heaven and in a far-off age, he had such great predecessors._(_41_)_ His resignation is of a world- and life-affirming character. He conceives of infinite Being not as something devoid of qualities, as the Indians do, but as life with a full content. The self-perfecting, therefore, for which man is to strive is not for him, as it is for them, in any way an anticipation of a state of death, but a living out of life which is guided by deep reflexion. An elegantly egoistic world- and life-affirmation speaks through him, as through Chwang-tse.

The efforts of the man who refuses to deceive himself about himself are not directed, therefore, to any sort of action which is recognized as serviceable, but are concerned with maintaining his own Being and giving it the fullest possible experience of life. Whatever good he does to others he never does for their sakes, but always for his own.

Spinoza rejects the achievement of modern ethics as influenced by Christianity, viz. the regarding of altruism as something that belongs to the essence of ethics, and confines himself to the thought that in the last resort all ethical action aims at our own interests, though it may be at our highest spiritual ones. In order to avoid thinking anything which is not a necessity of thought, he goes back of his own free will into the captivity in which ancient ethics lived.

If he could let himself go, he would, like Chwang-tse, conduct a campaign against the morality of love and duty. But since he already has as thoroughgoing opponents the [pg 119] authorities, the theologians, whether Jewish or Christian, and almost every philosopher, he has to speak cautiously and offer mankind without attracting notice the life-view which advocates profound and

thinking egoism.

Just as God, the totality of universal Being, acts not with any aim or object but from an inner necessity, so also does the man who has attained to insight. He does only what contributes to complete experience of life, nothing else. Virtue is capacity for self-maintenance at the highest level, and this self-maintenance is attained to when reason is the highest motive to action, and efforts after knowledge and freedom from passion take possession of the man and make him free, that is, allow his conduct to be determined by himself alone and on purely inward grounds. The ordinary man is unstable, moved hither and thither in all sorts of ways by outward causes, with no idea of his future fortune or his final fate, like a ship that is tossed about, now here, now there, on a stormy sea. Ethics, therefore, consists in living our life more in the form and fashion given it by thought than in bodily actuality.

Acting, therefore, with a deep, enlightened egoism and purely from intellectual impulses, a man behaves nobly in every relation of life. He strives to requite hatred, indignation, and contempt with love and noble feeling, because he knows that hatred causes him discomfort. He seeks at any price to create around him an atmosphere of peace. He never acts deceitfully, but always straightforwardly. He has no need to feel sympathy. Since he lives entirely under the guidance of reason, he does good whenever the opportunity offers, on principle, and therefore does not need to be roused to noble feeling by any experience of discomfort. In fact he avoids sympathy. Again and again he makes it clear to himself that everything that happens is brought about by some necessity in the divine nature and in obedience to eternal laws. Just as he finds nothing in the world which deserves hatred, mockery, and contempt, so he finds in it nothing to evoke sympathy. [pg 120] Man must be ever striving to be virtuous and happy, and if he is conscious of having done good within the limits of what is commanded him, he can with an easy mind leave his fellow-men and the world to their fate. Beyond the possibilities of his own immediate activities he need have nothing to do with them.

The wise man who practises the higher life-affirmation possesses power. He has power over himself, power over his fellow-men, and power over circumstances. How very similar is the tone of Spinoza's thought to that of Lao-tse, Chwang-tse, and Lie-tse!

Spinoza lives out his own ethic. In contented independence he passes his life, till consumption brings it to an early close. He declines an invitation to be lecturer in philosophy at Heidelberg University. He is strict with himself, but his resignation is lighted up by a mild trait of considered humanity and friendliness. The persecutions to which he is exposed fail to embitter him.

Intent though he is on thinking only in accordance with pure nature-philosophy, Spinoza does not concern himself so exclusively with the two natural entities, nature herself and the individual man, as do many of his Chinese predecessors, but maintains an interest in organized society. He is convinced that it betokens progress when men change, from the "natural" stage of society to the "civic." Being formed for living with his fellows, man is freer if he settles by general agreement what belongs to each, and what the relations are to be between himself and society. The State must, therefore, have power to issue general orders as to how people are to live, and to secure respect for its laws by means of penalties.

A real devotion of oneself to the common weal appears, however, to Spinoza not to be called for. According to him the perfect human society appears of itself just in proportion as its individual members live according to reason. In contrast, therefore, to his contemporary, Hobbes, Spinoza looks for the progress of society not to the [pg 121] measures taken by the authorities, but to a growth towards perfection in the dispositions of their subjects. The State is to educate its citizens not to submissiveness, but to the right use of freedom. In no way must it do any injury to their sincerity, and it must therefore tolerate all religious views.

Far as Spinoza goes to meet the spirit of the age, there is one point on which he cannot agree with it, viz. that there are ethical aims and objects, aims and objects practical and purposive, to be realized in the world.

Advancing far ahead of his contemporaries, he reaches a universal notion of ethics, and recognizes that from the standpoint of consistent thinking, every ethical relation is nothing but an expression of the relation of the individual to the universe. When, however, ethics have in this way become universal, they are faced by the question how the relation of the individual to the universe is conceivable as producing an effect upon the universe. On the answer to this question it depends whether a real activist ethic can be established, or whether the ethical is only so far present as resignation can be explained as ethical.

That is the reef which threatens danger to all nature-philosophy, and whenever a thinker imagines that with clever seamanship and a favourable wind he can sail round it without coming to grief upon it, he is nevertheless finally driven upon it, as by submarine currents, and suffers the same fate as his predecessors. Like Lao-tse and Chwang-tse, like the Indians, the Stoics, and all self-consistent thinkers before him, Spinoza is unable to furnish what ethics demand, viz. that the relation of man to the universe

shall be conceived of as not merely a spiritual relation, but as active devotion to it in the world of sense. The opponents of this solitary thinker are instinctively conscious that with the re-establishment of an independent nature-philosophy there appears something which means danger to the optimism and the ethics of their world-view. Hence [pg 122] we find in the seventeenth and eighteenth centuries everyone uniting to suppress Spinoza's philosophy.

It is on behalf of optimism that the age is most troubled. The terrible earthquake which in 1755 destroyed Lisbon, sets the mass of men asking whether the world is really ruled by a wise and kindly Creator. Voltaire, Kant, and many other thinkers of the age seize on the occurrence as a topic for discussion, partly confessing their perplexity, partly seeking new ways out of the difficulty for their optimism.

Leibniz's optimistic-ethical world-view side by side with nature-philosophy

How little optimism and ethics have to expect from a real nature-philosophy is shown not only in Spinoza, but also in Gottfried Wilhelm Leibniz (1646-1716)._(_42_)_ In his _Theodicée_ (1710) he tries to be fair to the optimistic world-view. He is helped in this by the fact that his nature-philosophy is much more living and adaptable than Spinoza's. He is also determined to employ every possible device to attach an optimistic meaning to reality. He nevertheless gets no further than a laborious establishment of the conclusion that the actually existing world is the best of all possible ones.

Moreover, so much of optimism as he rescues is useless for his world-view because it contains no energies which can be directed to ethical action upon the world. When he is consistent with himself he remains, like Spinoza, a prisoner within nature-philosophy. All the difficulties for ethics which Spinoza's deterministic nature-philosophy contains within itself, are to be found also in his. Owing to the fact that he does not put the union of thought (spirit) and extension (matter) far away in the Absolute, but allows it to be realized in countless tiny individualities [pg 123] which in their totality constitute the universe—he calls them monads—his nature-philosophy corresponds to the multiform character of reality much better than Spinoza's does. He anticipates to a considerable extent the modern nature-philosophy which is based on the cell-theory of matter. Yet he, too, remains under the spell of the way the problem is put by Descartes. He does not allow the individualities in which thought and extension are united, to enter into living relations with each other, but limits their existence to being merely forces with powers of conception. Their being consists in being conscious of the universe, more clearly some, more confusedly others, but each independent of the rest.

In Spinoza there is a possibility of reaching an ethic, inasmuch as an attempt can be made to give an ethical interpretation to the mystical relation between man and the Absolute. Leibniz bars this path against himself in that he does not recognize such an abstract Absolute as the content of the universe. It is, therefore, not the result of chance that he nowhere philosophizes searchingly about ethics. In no way can an ethic be deduced from his nature-philosophy.

Instead of admitting to himself this result and unfolding the problem of the relation between ethics and nature-philosophy, he weaves into his philosophy traditional dicta about ethics, and defines the Good as love to God and man.

In nature-philosophy Leibniz is greater than Spinoza, because he deals with living reality more thoroughly than the latter does. In the struggle for a correct world-view, however, he is far behind him, because Spinoza, a man with a simpler mental endowment than his, recognizes the reconciliation of ethics and nature-philosophy as the central problem of world-view, and proceeds to deal with it.

If Leibniz had remained consistent, he would have ended in atheism, as does the Indian Samkhya philosophy, which similarly makes the world consist of a multiplicity of [pg 124] eternal individualities. Instead of that, he introduces into his nature-philosophy, in order to rescue for himself a satisfactory world-view, a theistic notion of God, and by giving it an optimistic, ethical, and theistic expression, he makes it acceptable to the eighteenth century. His philosophy, popularized till it is almost unrecognizable by Christian Wolff (1679-1754), helps to lay the foundations of German rationalism.

But in spite of the treason of which he is thus, though with the best intentions, guilty against nature-philosophy, Leibniz cannot undo the fact that thinking on nature-philosophy lines awoke at that time to activity through him. Without wishing it, he too contributes to making Spinoza an influence.

But to let oneself be mixed up with nature-philosophy is for the spirit of the time to step into the dangerous unknown. It therefore resists as long as possible. At last, however, since Kant and Spinoza together are undermining the optimistic-ethical world-view of rationalism which has been built upon the real world and so conveniently fitted up, it has to make up its mind to rebuild, and attempt the process of arriving at a conception of optimism and ethics by direct thinking on the essential nature of the world. For the

carrying out of this undertaking the German speculative philosophy offers its services.

[pg 125]

CHAPTER XI

J. G. FICHTE'S OPTIMISTIC-ETHICAL WORLD-VIEW

Speculative philosophy and Gnosticism

THE vision of an optimistic-ethical philosophy cast in one mould hovers in front of speculative philosophy, which hopes to discover the meaning of the world by the most direct route. It will have nothing to do with analysing the phenomena of the universe in order to deduce its nature from them. It proceeds deductively, not inductively. In pure abstract thinking it hopes to learn for itself how the real world has evolved out of the notion of Being. It is imaginative nature-philosophy in a logical dress.

The right to deal with the world in this fashion is derived by speculative thought from the results of the theory of knowledge, according to which the world as we observe it is more or less our own representation of it. We have, somehow or other, a creative share in its coming into existence. It follows that the logic which is the rule with the finite ego is to be conceived as an emanation of that which holds good with the Absolute. The individual is therefore entitled to disclose in his own thinking the motives and the process of the emanation of the empirical world out of the notion of Being. Speculation, or in other words constructive logic, is the key to the secret door into knowledge of the world.

Generically, speculative German philosophy is essentially related to the Græco-Oriental Gnosticism, which in the first centuries of the Christian era advances its views concerning the emergence of the sensible world from the world of pure Being._(_43_)_ The Gnostic systems aim at establishing a world-view [pg 126] of redemption. They concentrate on the question how the spiritual individualities which find themselves in the material world came there, and how they can return from it into the world of pure Being. Speculative German philosophy on the other hand tries to obtain such a knowledge of the world as shall give a meaning to the activities of the spiritual individualities in the world. Speculative thinking at the beginning of the Christian era is dualistic and pessimistic; that at the beginning of the nineteenth is monistic and optimistic. In both cases, however, the method of obtaining the world-view is the same.

Among the representatives of the speculative philosophy the most eminent are: Johann Gottlieb Fichte (1762-1814), Friedrich Wilhelm Joseph Schelling (1775-1854), and Georg Wilhelm Friedrich Hegel (1770-1831). It is only Fichte and Hegel, however, who produce world-views with a characteristic stamp of their own. Schelling gets no further than a nature-philosophy, and stands almost completely aside from the struggle for an optimistic-ethical world-view with which his age is occupied. Kept in a perpetual state of flux, his thinking makes use of all possible starting-points one after another and is now more concerned with natural science, now more akin to Spinoza's thought, and now to Christian. He never makes a definite, conscious attempt to found an ethic.

Fichte's speculative founding of an ethic and of optimism

Fichte begins as the antipodes of Spinoza._(_44_)_ He aims at extracting from the universe a confession that it is a purely [pg 127] optimistic ethical one, by thinking Kant's thoughts out to a conclusion.

Kant, according to him, made the mistake of not bringing his two discoveries, viz. epistemological idealism and the ethic of the categorical imperative into that inward connexion with one another in which they really stand.

What is the meaning of the fact that the moral law and the sensible world both become actual in me? That is the starting-point of Fichte's philosophizing.

Through the categorical imperative I experience that my particular ego is a self-determined will to activity. Correspondingly, every "thing in itself" which I assume to exist behind phenomena as the real on which they are based, is similarly a self-determined will to activity. The essential nature of infinite Being also can consist of nothing else. The universe is, therefore, the phenomenal form of an infinite, self-determined will to activity.

Why does the absolute Ego appear as a phenomenon in a sensible world? Why is Being revealed as Becoming? If I understand this, I have comprehended the meaning of the world and of my own life.

Now the absolute Ego, because it is infinite will to activity cannot persist in being merely an Ego. It establishes a non-Ego to be a limit to itself in order that it may again and again overcome it, and thereby become conscious of itself as will to activity. This proceeding takes place amid the multiplicity of finite rational beings. In their power of intuition the sensible world becomes actual, and in their overcoming of it they recognize a duty which makes itself mysteriously felt within them and unites them with the world-spirit. This is the meaning of the philosophy of the identity of Ego and non-Ego.

It is not only, then, that the world exists merely in my mental creation of it: it is, further, only produced in me in order that I may have something on which my will to fulfilment of duty can exercise itself. The phenomena of becoming and disappearing which I project out of myself [pg 128] exist only that I may through them comprehend myself as an ethical being. In this way epistemological idealism and the categorical imperative, when they act together and one climbs on the shoulders of the other, can look behind the curtain which hides the secret of the world.

Kant protests against the idea that Fichte's system is to be considered the completion of his philosophy. As a matter of fact, however, Fichte does with ingenious art continue the lines which were begun in the _Critique of Pure Reason_ and the _Critique of the Practical Reason_, and think out the ideas of the philosopher of Königsberg to a self-contained world- and life-affirming ethical world-view. He presents them in a generally intelligible form in _The Destiny of Man_, published in 1800. This book is one of the most powerful documents produced by the struggle for an ethical world-view.

Fichte gives a content to the abstract, absolute duty of Kant, making it consist in this, that man, as the instrument of the ever-active absolute Ego, assigns to himself the destiny of working with the latter "to bring the whole sensible world under the sovereignty of reason."

Since his fundamental moral principle possesses a content, Fichte is able to deduce particular demands from it, but that content is so general and vague that the code of duty which is drawn out from it has but little vital force. Nothing can really be got out of this fundamental principle beyond the demand that man shall in every situation of life fulfil the duties which from time to time fall to him as a result of his destiny of having to help forward the sovereignty of reason over nature. Fichte therefore distinguishes the general duties which man, as such, has to fulfil, and the special ones which are incumbent on him according to his natural gifts, his social position, and his profession. The latter are emphasized as specially important.

By defining ethics as activity which aims at subjecting the sensible world to reason, Fichte gives a cosmic formulation to the utilitarian ethic of rationalism, and thus [pg 129] produces a comprehensive and deep foundation for the ethical enthusiasm which was a discovery of his time. In this matter also he carries through something which hovered before the mind of Kant.

Thereby he opposes the representatives of the popular philosophy of the Illumination, and in a polemical pamphlet he criticizes very severely Christoph Friedrich Nicolai. At bottom, however, the only reproach he can level at them is that they wish to go on housing ethics and belief in progress in the naïve world-view arrived at by the healthy human reason instead of accepting both of them from the world-view produced by the union of epistemological idealism and the categorical imperative. To persist in imperfect rationalism when the perfect has been made a reality by Kant and himself is, in his opinion, a crime against truth. To him the beginning of wisdom is insight into the paradox that "consciousness of the world of actuality springs from our need of action and not, _vice versâ_, our need of action from our consciousness of the world."

The spirit of Fichte's world-view, then, is completely that of rationalism, only that it believes it has found itself at home with him in the real nature of Being, and now comes forward with still stronger conviction and a still more burning enthusiasm. In Fichte's writings, men are positively driven with the lash to work for the improvement of the world. With impressive pathos he teaches them to obey the inner voice which urges them on to activity, and indicates to them their definite duty whatever may be the special circumstances of their existence, and to recognize in so doing that they are thus fulfilling the highest, and indeed the only destiny of their lives.

It is as the result of this inner urge to activity that we long for a better world than the one which we see around us, and belief in that better world is the food by which we live. Fichte makes confession of unbounded optimism. "All those outbreaks of untamed force before which human power is annihilated, those devastating hurricanes, [pg 130] those earthquakes, those volcanic eruptions, can be nothing else than the last wrestlings of the wild mass of nature against the uniformly progressive, purposive, and life-promoting course to which, in opposition to its own tendencies, it is being compelled." . . . "Nature is to become to us more and more transparent and capable of examination even to its innermost secret, and enlightened human power, armed with its own inventions, is destined to master it without trouble, and then to exploit peacefully its once for all made conquest."_(_45_)_ Here Fichte gives us

the triumphant pagan of the belief in progress which the spirit of the modern age, that lives on the achievements of its knowledge and power, has been composing since the Renaissance. He is as thoroughly convinced as the staunchest rationalist that nature is the buffalo which has remained refractory so long, but will at last be brought beneath the yoke.

That mankind will perfect itself and reach a condition of unbroken peace, is to him as certain as the perfection that nature will one day arrive at. At present, it is true, we are in a period of arrested progress with temporary setbacks, but when this is past, and all useful things which have been discovered at one end of the world, get known to and distributed to all, then mankind, using its powers in complete co-operation and marching forward in step, will raise itself uninterruptedly, without arrest of progress or setback, to a culture of which we can form no conception.

To the State Fichte assigns in his early writings a not very important _rôle_, but in his later ones a great one. In _The Foundations of the Law of Nature_ (_Grundlage des Naturrechts_) (1796), it is for him only the maintainer of law and order. In his work _The Complete Commercial State_ (_Der geschlossene Handelsstaat_), which appeared in 1800, he allows it to organize industry and to take over social duties. In his _Addresses to the German Nation_ (_Reden an die deutsche Nation_, 1808), he makes it a moral educator and a protector of the virtue of humanity.

[pg 131]

The man who, with the help of epistemological idealism, has made his way through to the higher rationalism, is safe from losing his optimism, even though he goes through the cruellest experiences. He has grasped the fact that the sensible world is only the limit which the infinitely active will has created on purpose to be overcome. This lends him inward independence in the face of all happenings. He has no need to understand them individually. He can let a large proportion of them be put aside as puzzling to his finite spirit. What is essential he knows: viz. that what is real in the world is not matter, but spirit only.

Partaking of the eternally active spirit, man is raised above the world, and is eternal. The sufferings he meets with afflict nature only “with which he is connected in a marvellous way,” but not himself, the being who is exalted above the whole of nature. Of death he has no fear. He does not die to himself, but merely to those who survive him. . . . “All death in nature is birth. . . . Nature is throughout nothing but life. It is not death which kills, but the living life which, concealed behind the old one, now begins and proceeds to develop. Death and birth are nothing but the struggle of life with itself in an effort to reveal itself more and more clearly and more and more like its real self.” It is in similar words that the Chinese monist, Chwang-tse, announces that life is eternal and the dying of an individual only means that one existence is being re-cast to form another. .

Fichte’s mysticism of activity incapable of being carried through

Fichte’s philosophy of absolute activity is the expression of his own strong ethical personality, which with impetuosity and self-sacrifice takes problems in hand, and uses itself up in the strain involved. But even he is unable to make a genuine combination of epistemological idealism and ethical so as to produce an ethical world-view which is a [pg 132] necessity of thought. The impossibility of the undertaking reveals itself everywhere.

In order to conceive ethics as a part of the normal course of world-happenings, Fichte, like all others who make the same attempt, gives up as hopeless any differentiation between human action and world-happenings. The world-spirit’s impulse to activity, he says, experiences itself in man as will to ethical action. But, indeed, the whole world is filled with this will to activity which is for ever surging against the limitations it has set up for itself. Everything that happens is only an expression of it. What difference, then, is there between natural happenings and ethical? Between activity in itself and ethical activity? Purposive activity directed with knowledge and intention to the subjection of the sensible world to reason is ethical, decides Fichte. But what does that mean, when closely examined? It means that the finite spirit becomes moral by entering into and taking seriously the play of the infinite spirit which aims at overcoming its own self-created limitations. Looking in this way at Fichte’s thought, we see clearly that with the world-view which results from the combination of ethical and epistemological idealism, ethics have no longer any meaning.

Again, what is the meaning of “bringing the whole of the sensible world under the sovereignty of reason”? This conception of the ethical is not only too wide, but fantastic also. To a limited extent man is able to harness the forces of nature for his service, and with a little stretching of language he can, with Fichte, describe such action as not purposive merely, but also in the widest sense ethical. Upon this terrestrial globe he has some “influence,” but upon the world none. That he gives names to the mighty heavenly bodies and can calculate the orbits of many of them, cannot mean that he brings them under the sovereignty of reason. Upon deep-sea life, too, he exercises no other influence than catching specimens of it and giving them names.

That he may be able to assert that there is such a thing [pg 133] as an ethical purpose in the world, Fichte falsifies the world's birth certificate, and gives it the categorical imperative for father and epistemological idealism for mother. But this is of no use. The ethical purpose thus produced cannot satisfy ethical thought.

By conceiving the infinite spirit, in which the finite spirit has a share, as will to activity, Fichte tries to make possible a world-view of ethical world- and life-affirmation. In reality, however, this takes him no further than a more emphatic world- and life-affirmation, into which, with the help of speculative thought, he smuggles the idea of duty, thereupon proclaiming it to be ethical. It fares with him just as with the Chinese philosophers, who similarly exert themselves in vain to produce an ethic out of world- and life-affirmation.

Absorption in the Absolute by means of action is, as Fichte thinks, something prodigious, but, just like its counterpart, absorption in the Absolute which is effected by an act of thought, it is not ethical but supra-ethical. The element which is needed by the mysticism of absorption in the Absolute to make it ethical cannot be secured either by enhancing or by depreciating the will to activity.

Fichte's mysticism of activity in which man lets loose his energy in the world is related to the ethic of deed, just as Spinoza's mysticism of knowledge in which man is absorbed in the world is related to that of self-perfecting, but it is only very incompletely that either can develop itself into a real ethic.

The absorption in the Absolute which comes into actuality in an act of thought lies nearer to nature-philosophy than that which completes itself in an active deed. The Brahmans, the Buddha, Lao-tse, Chwang-tse, Spinoza, and the mystics of every age, have experienced the becoming one with the Absolute as a coming-to-rest in it. Fichte's mysticism of activity lies more in the path of dualistic thinking than in that of real nature-philosophy. It is something which has been extorted by enthusiasm, but Fichte [pg 134] is devoted to it, and rightly, because he has a feeling that the interests of an active ethic are better guarded by it than by the other. Since, however, he thus once and for all decides for a nature-philosophy, he comes, dominated though he is by the ideal of an active ethic, more and more to the natural quietist consequences of a nature-philosophy. He goes through a process of evolution which brings him nearer to Spinoza's world-view. In his _Instruction Concerning the Blessed Life_, which appeared in 1806, six years later than _The Destiny of Man_, it is to him no longer the ethical which in itself is the highest, but the religious. The ultimate meaning of life, as he now recognizes, is not to act in God, but to be merged in Him. "Self-annihilation is the gateway into the higher life."

He believes, indeed, that he is thereby merely deepening his world-view without diminishing its ethical energy, and he remains himself, right to the end, the fiery spirit which consumes itself in activity for promoting the progress of the world. But his thought has bent under the weight of nature-philosophy. Without clearly admitting it to himself, he recognizes that out of nature-philosophy there can be drawn only an intellectual, not an ethical meaning for the world and life. Spinoza observes with a smile how he retires upon the thought beyond which a nature philosophy cannot advance.

Fichte is the first philosopher to declare plainly that no world-view is ethical which does not enable man to explain that an enthusiastic active devotion to the universe is something grounded in the nature of the world and of life. But the road he takes in order to develop this thought leads him astray. Instead of going more deeply into the question how ethical happenings, though coming from the world-spirit, and directed upon the world, are nevertheless different from normal world-happenings, and investigating the nature of this difference, he employs the trick, which had been made possible by Kant, of declaring, with the help of epistemological idealism, that the ethical world-view is a necessity of thought. Many of his contemporaries [pg 135] believe with him that it has thereby really reached a position of supremacy, and even those who cannot go with him the whole length of the philosophy of the Ego and Non-Ego, are gripped by the force of the ethical personality which speaks from Fichte's writings.

The direct effect, then, of Fichte's philosophy is that the optimistic, ethical spirit of rationalism maintains its position and becomes stronger and deeper. His philosophy is a source of inspiration which produces a mighty impulse to ethics and civilization. But the vessel in which, with a magnificent wind behind him, he starts with his companions on a voyage over the sea of knowledge is a leaky one. A catastrophe is only a question of time.

Fichte's belief that he has obtained from the nature of the universe the living compulsion to ethical duty and ethical work which he feels within himself, is an illusion. The manner, however, in which he conceives the problem of the optimistic-ethical world-view, and perceives that for its solution the ordinary processes of life afford no help, so that more or less violent ones must be allowed to take their turn, reveals him as a great thinker.

[pg 136]

CHAPTER XII

SCHILLER; GOETHE; SCHLEIERMACHER

Schiller's ethical world-view; Goethe's world-view based on nature-philosophy

VERY important is the fact that the deepened optimistic-ethical world-view of Kant and Fichte finds a champion in Friedrich von Schiller (1759-1805), who brings it to the mass of the people with the force, added by poetical language. He is himself philosophically gifted, and undertakes in addition to develop it further. He wishes to broaden the foundation of the ethical by showing its relation to the æsthetic.

In his _Letters Concerning the Æsthetic Education of Mankind_ (1795), he works out the idea that art and ethics belong together as far as this, that man maintains with the sensible world a relation which is free and creative. "The transition from the passive condition of feeling to the active one of thinking and willing comes about in no other way than through an intermediate condition of æsthetic freedom. . . . There is no way of making the sentient man rational other than first making him æsthetic." In what way the capacity for freedom which is built up in man by æsthetic practice really disposes him to morality, Schiller does not work out in further detail. His treatise, in spite of all the notice it attracted and deserves, is more rhetorical than substantial. He has not gone to the bottom of the problem of the relations between the æsthetic and the ethical.

In contrast to Schiller, Johann Wolfgang von Goethe (1749-1832), stands in almost as cold an attitude to the world-view of the deepened rationalism as he does to that of ordinary rationalism. To him it is impossible to share [pg 137] the confidence with which others, looking around, regard optimistic and ethical convictions as well founded. What separates him from Kant, and Fichte, and Schiller, is reverence for the reality of nature. Nature is to him something in herself, not merely something existing with a view to mankind. He does not require from her that she shall fit herself completely into our optimistic-ethical designs. He does no violence to her either through epistemological and ethical idealism or through presumptuous speculation, but lives in her as a human being who looks at existence with wonder and does not know how to bring her relation to the world-spirit within any formula.

Descartes led modern philosophy astray by cutting the world up into objects which have extension and objects which think, and by going on, moreover, to refuse to each of them the possibility of influencing the other. Following in his steps, thinkers rack their brains over the problem of these two parallel kinds of existence, and try to embrace the world in formulas. That the world is life, and that in life lies the riddle of riddles, never enters their minds. Hence they overlook in their philosophizing what is most important. Because Descartes preceded them, the two great spirits who adhere to nature-philosophy, Spinoza and Leibniz, cannot get further than a nature-philosophy which is more or less dead. Being in the line of descent from Descartes, Kant and Fichte renounce all philosophizing over the real world.

Descartes and the ethical belief-in-progress, therefore, agree in a common neglect of nature. Both alike overlook the fact that she is living, and that she exists for her own sake, and it is because he cannot join them in this that Goethe dares to confess that he understands nothing about philosophy. His greatness is this: that in a time of abstract and speculative thought he had the courage to remain elemental.

Overwhelmed by the mysterious individual life in nature, he persists in maintaining a magnificently imperfect [pg 138] world-view. With the spirit of an investigator he looks within into everything; in that of an inquirer he looks around upon everything. He wants to think optimistically. Shaftesbury's thoughts exercise their charm upon him also. But in the chorus of optimism which makes itself heard so loudly around him, he cannot join. World- and life-affirmation is for him not such a simple thing as it is for Fichte and Schiller. He strives to reach an ethical world-view, but admits to himself that he cannot carry it through, and he therefore does not venture to attribute a meaning to nature. To life, however, he will attribute one. He seeks it in serviceable activity. To make the world-view of activity at home in nature-philosophy is to him an inner necessity. The conviction that activity provides the only real satisfaction that is to be found in life and that therein lies the mysterious meaning of existence is shown by him in _Faust_ as something which he has laboriously gained during his pilgrimage through existence and to which he will hold fast, without being able to explain it completely.

Goethe struggles to arrive at a conception of ethical activity, but cannot reach one because nature-philosophy is unable to provide him with any criterion of what is ethical. What that philosophy had to refuse to the Chinese monists and to Spinoza, she cannot give to him either.

The range of this world-view of Goethe's which deals thus with reality remains hidden from his contemporaries. Its incompleteness alienates their sympathies and irritates them. For knowledge of the world and of life which cannot be reduced to a system, but sticks fast in facts, they have no understanding. They hold to their optimism and their ethic.

Schleiermacher's attempt at a nature-philosophy

Daniel Ernst Schleiermacher (1768-1834), stands apart both from the ordinary and from the deepened rationalism because he cannot free himself from the influence of [pg 139] Spinoza._(_46_)_ His life-work is directed to preaching the Spinozan nature-philosophy as being, as far as he can make it so, both an ethic and the Christian religion. Hence he always dresses it up as one or the other of these.

The accepted ethical code, in Schleiermacher's opinion, makes man merely run about the earth as an ethical individual bent on improving the world. Living in this way, in a constant state of enthusiasm, he becomes in danger of losing himself and becoming unpersonal. He forgets that his primary duty is, first of all to be alone with himself, to look within himself, and, instead of being a mere human creature, to make himself into a personality.

This renunciation of rationalism's enthusiasm for activity is to be found in the _Monologues_, those splendid introspective meditations meant for the first New Year's Day of the nineteenth century. One seems to hear in them Lao-tse and Chwang-tse criticising the moralism and the fanaticism for progress of Confucius.

Man's first task is, according to Schleiermacher, to realize his oneness with the Infinite and in the Infinite to see the world. Only that which results from this as action is really significant, and has importance for morality.

Spinoza's ethic consisted in keeping oneself at the highest level and living one's life more after the fashion of a life of thought than after that of a life of corporeal existence. Schleiermacher's ethic has the same objective except that he seeks to combine with it a more comprehensive interest in the world than is to be found in Spinoza. He is helped in this direction by his belief that progress is something immanent.

We have, he says, no other perfecting to bring about in things than that which is inherent in them. Ethics, therefore, are not a setting up of laws, but the recognition and the description of the tendencies working for perfection which appear in the world itself, together with behaviour [pg 140] in accord with their spirits. The moral law is not distinct from the law of nature and pursues no other aims than the latter does. It is only the law of nature arriving in man at the consciousness of itself.

Schleiermacher, therefore, feels that his task is not, as Fichte conceived his to be, the bringing of the universe under the sovereignty of reason; it consists solely in supporting the oneness of nature and reason in the sphere of human action, which is ever striving to realize itself within that universe. "All ethical knowledge is the expression of the ever-beginning but never completed efforts of reason to become nature." Ethics are a contemplative "science." They revolve around the two poles of natural science and human history.

The ethic which results from this fundamental conception is, like those of Lao-tse and Chwang-tse, so toned down that there is no longer any real power in it. However completely Schleiermacher may try to conceal this fact by his wonderful powers of description, it plays only a subordinate _rôle_. What gives a meaning to human existence is something which is independent of deeds; it is the oneness with the Infinite which is experienced in feeling.

With its clever dialectic, but not in reality, Schleiermacher's ethic shows itself finally to be superior to that of Spinoza. His world-view is that of Spinoza, only enriched by his belief in the immanence of the power of progress. Hence his ethic is iridescent with somewhat more brilliant colours.

Thus do a living nature-philosophy in Goethe and a Spinozan one in Schleiermacher undermine the ground on which stand the men of the now beginning nineteenth century, whose thinking is so enthusiastically optimistic-ethical. The crowd pays no attention to their dangerous proceedings. It gazes at the fireworks which Kant and Fichte let off, while Schiller recites his poetry. And now there begin to rise bursts of rockets which throw a peculiarly brilliant light. The past-master in the art of firework display, Hegel, has come into action!

[pg 141]

CHAPTER XIII

HEGEL’S SUPRA-ETHICAL OPTIMISTIC WORLD-VIEW

Ethics in Hegel’s nature-philosophy, and in his philosophy of history

IN his speculative philosophy Fichte’s first and chief interest was ethical. Hegel, deeper and more objective than he, aims at truth before everything._(_47_)_ While using any helpful considerations which are provided by facts, his aim is to discover the meaning of Being. He therefore cannot join Fichte in the violent procedure, suggested by his ethic, of giving the world the categorical imperative for father and epistemological idealism for mother. Before going so far as to write out a birth-certificate for the world, he undertakes some material investigations. He studies the laws which govern events, as they are revealed in history. He then lays these as the foundation for the constructive operations which are to explain the origin of the world out of the notion of Being. His philosophy, therefore, is a philosophy of history become cosmic. The building, so far as one can measure it externally, is solidly constructed. That is why it is still convincing even where its lines lose themselves in infinity.

What, then, does Hegel discover to be the principle underlying the course of events in history? He discovers that every process of becoming advances with natural progress, and that this progress realizes itself in the occurrence of a consecutive series of contradictions which invariably issue in reconciliation! In thoughts as in facts, [pg 142] every thesis evokes an antithesis. Then these unite in a synthesis which preserves what is valuable in either of them. Every synthesis that is reached becomes again a thesis for a new antithesis. From these there results again a new synthesis, and so on for ever.

With the aid of this scheme Hegel can expound the course of history. From it he is also able to develop the basic principles of logic. Hence he is sure that from it it must be possible to make intelligible how the notional world which can be logically developed out of the notion of Being passes over into being the world of reality. He carries this fancy through to its conclusion in such magnificent fashion, that even we, who are proof against its charm, can understand how it was possible to become intoxicated with it. JASON AND MEDEA _Is there a Sex War?_

A feature of modern life is that matrimonial quarrels, like modern war, are carried on on a large scale, involving not individuals, nor even small groups of individuals, but both sexes and whole classes of society. In the past, Jason and Medea, neither of them quite an exemplary character, measured their strength against one another as individuals; and, though each voiced the wrongs and the naked brutality of their sex, it did not occur to either to seek in politics or in social reform a solution or a compromise. Jason, indeed, as the reactionary face to face with a turbulent and insurgent female, called to his aid the powers of kingship and the State——to suppress and exile, but not to remedy. Medea, driven mad——like so many able and remarkable women——by the contempt and ingratitude of men as individuals or in the mass, and aware that the law was a mockery where she was concerned, expressed herself in savage protest after the manner of a militant suffragette. While I can open my newspaper to-day and read of mothers desperate with hunger, misery, or rage drowning themselves and their children, I cannot bring myself to look upon Medea as some elemental being from a dark and outrageous past. As for Jason, he never did appear to anybody as other than an ordinary male.

During the last twenty or twenty-five years, when women were struggling for their right as citizens to a vote and to a decent education, began what has been called the sex war. No woman would deny that we began it, in the sense that we were rebels against a system of masculine repression which had lasted almost unbroken since the beginning of history. In a similar sense, the proletarian to-day begins the class war. Those who remember the heroic battles of suffrage days know that the sequence of events was as follows: We made our just demands and were met with ridicule. We followed with abuse——all the pent-up anger, misery, and despair of centuries of thwarted instinct and intelligence. Man retaliated with rotten eggs. We replied with smashed windows; he with prison and torture. People forget so readily, that it is well to remember that this was in the immediate past; it is not a nightmare picture of one of those future sex wars with which our modern Jasons delight to terrify the timorous of both sexes.

Is there a sex war? There has been. It was a disgraceful exhibition, and would not have come to a truce so soon, but that it was eclipsed by the still more disgraceful exhibition of the European War. In 1918 they bestowed the vote, just as they dropped about a few Dames and M.B.E.'s, as a reward for our services in helping the destruction of our offspring. Had we done it after the fashion of Medea, the logical male would have been angry. They gave the vote to the older women, who were deemed less rebellious. Such is the discipline of patriotism and marriage, as it is understood by most women, that the mother will sacrifice her son with a more resigned devotion than the younger woman brings to the loss of her lover. There may be more in this than discipline. If honesty of thought, speech, and action were made possible for women, it might transpire that on the average a woman's love for her mate is more compelling than love for her offspring. Maternal instinct——genuine, not simulated——is rarer, but, when found, more enduring.

There was a promise, as yet unredeemed by any political party——for the politician has yet to be found who will realize that the sex problem is as fundamental in politics as the class war, and more fundamental than foreign trade and imperial expansion——to extend this franchise on equal terms with men. "Good fellowship" between the sexes as between classes was the key-note of the war. It was held that women had proved their mettle and that mutual aid was to be the basis of all future activities, public and private. The sex question was deemed settled, and everyone was led to suppose that all inequalities would be gradually eliminated. On this partial victory and this promise feminists called a truce, and abandoned the tactics of militarism.

But you never know where you have Jason. He was a soldier, mark you, and a gentleman. Forbidden open warfare, he takes to sniping. He snipes the married women out of those posts for which they are peculiarly fitted——as teachers or maternity doctors——although it is against the law to bar women from any public activity on the ground of marriage. He cheats unemployed women out of their unemployment insurance more craftily and brutally than he cheats his fellow-men. Instead of realizing that the competition of women in industry and the professions is a competition of population pressure rather than of sex, he seeks by every means in his power to drive woman back to matrimonial dependence and an existence on less than half a miserably inadequate income; and then he mocks at her when she claims the right to stem the inevitable torrent of children whose advent will but aggravate man's difficulties as well as her own. But worse than all the sniping is the smoke-screen of propaganda. While feminists have, in a large measure, stayed their hand, anybody who has anything abusive to say of women, whether ancient or modern, can command a vast public in the popular press and a ready agreement from the average publisher.

It is a very insidious propaganda. Thus the fashion-papers tell us that grandmamma’s ways are coming back into their own; elsewhere we are flattered for the frank honesty of the modern girl and then warned not to ask for equal pay or opportunity.[1] Again, we hear that woman, like the Labour Party when in office, has done nothing with the opportunities given her by the vote; or that the country rejectedThe Project Gutenberg eBook of An essay in defence of the female sex

TO MY READERS.

I do not know how better to use the space that the printer always leaves me in this part of the book than to redeem the promise I made at the end of my last novel, and tell you in a few words what became of Blanche Brixton Fantelli and her husband.

But, do you really need to be told?

Could they have done anything else than live in connubial felicity, after the man had proved himself so noble and the woman had learned to appreciate him at his true worth?

Well, whether they could or not, they didn't. Blanche is the happiest of wedded wives. She still holds to her theory that marriage is based on wrong principles, and that the contract as ordinarily made is frightfully immoral; but she says if all men were like "her Jules" there would be no trouble.

In this she proves herself essentially feminine. She is learning, albeit a little late, that man was not made to live alone, and that the love a mother feels for her child is not the only one that brings joy to a woman's breast.

Fantelli does not claim that Blanche is his property. He is her lover still, even though he has gained the law's permission to be her master. He recognizes that she has rights in herself that are inviolable. This is why they live together so contentedly. She would not be his mate on any other terms.

If it is not the ideal existence, it is very near it. As near as a man and woman who care for the world's opinion can live it in these days.

And now, with heartfelt thanks for the continued favor of the reading public, which I am conscious is far beyond my desert, I bid a temporary farewell to American shores. By the time this book is on the shelves of the dealers I shall be on European soil, there to remain, I trust, for the better part of a year. Wherever I am, my thoughts will always turn to you who have made these journeys possible, and there as here my pen will continue devoted to your service.

ALBERT ROSS.

Cambridge, Mass., _June 1, 1895._

A BLACK ADONIS.

CHAPTER I.

A REJECTED MANUSCRIPT.

"A letter for Mr. Roseleaf," he heard his landlady say to the chambermaid. And he was quite prepared to hear the girl reply, in a tone of surprise:

"For Mr. Roseleaf! This is the first letter he has had since he came."

The young man referred to stood just within his chamber door, waiting with some anxiety for the letter to be brought to him. He was about twenty years of age, of medium height, with rather dark complexion, curling hair and expressive eyes, and with a natural delicacy of manner that made him seem almost feminine at first view.

He had the greatest possible interest in the letter that the postman had just brought, but he was far too polite to disturb the landlady or her servant, who were not yet through with it.

"You can see that it is from a publishing house," commented Mrs. Ranning, inspecting the envelope with care. "It is from Cutt & Slashem, who bring out more novels than any other firm in the city. I told you he was some kind of a writer. Perhaps they are going to publish a book for him! If they do he will leave us for finer quarters. Novelists make a mint of money, I have heard. We must do our best to keep him as long as we can. Be very polite to him, Nellie. He appears to be an excellent young man."

Shirley Roseleaf's anxiety to get possession of his letter was not lessened by this conversation. It seemed as if his entire future hung on the contents of that envelope tarrying so long in Nellie's hands. The great publishers, Cutt & Slashem, had had a manuscript of his in their hands for nearly a fortnight. When they had definitely accepted it, his path would be perfectly clear. If they rejected it--but he had not got so far as that.

The manuscript was a romance--a romance of love! Its author had spent a great deal of time upon it. He had rewritten it with care, and finally made a neat copy, of which he was very proud. Then he had thought a long time over the question of a publishing firm. Cutt & Slashem stood at the top of their profession, and they finally received the preference. With the MSS. Roseleaf sent a pretty note, in which he included a delicate compliment on their success. The MSS. and the note were arranged tastefully in a neat white package and tied with pink twine.

After all of those precautions it is no wonder that the novelist felt surprise when days passed and no reply was sent to him. But never at any time was he discouraged. Had they intended to reject the novel, he reasoned, they could as easily have done so in three days as ten.

He pictured the members of the firm hugging themselves over their good fortune, passing the manuscript from one to the other, all eager for a taste of such a marvelous work. He did not think it egotism to believe they did not get stories like that every day.

His thoughts flew rapidly as Nellie slowly climbed the stairs. Now he would be famous, he would be courted, he would be envied! He would also be very, very rich, though that was not of so much account.

As Nellie handed him the letter he responded to her pleasant smile with one of his own, and even pressed a twenty-five cent piece into her hand. Then he closed his door behind him, bolting it in his eagerness to be alone. The morning was foggy, and he sank into a chair by the window, the only part of the room where he could see to read distinctly.

There was an attraction about the envelope. It was light buff in color, bearing the address of Cutt & Slashem in large letter on one side of the front face, besides the names of several of the most famous authors whose publishers the firm had the happiness to be.

"Shirley Roseleaf!" It would not look so badly in print.

So lost was he in the pleasant pictures which these thoughts conjured up that it was some minutes before he tore open the envelope. Then his astounded eyes rested upon these lines:

"Messrs. Cutt & Slashem regret to be obliged to decline with thanks the MSS. of M. Shirley Roseleaf, and request to be informed what disposition he desires made of the same."

Roseleaf read this dizzily. For some moments he could not understand what that sentence meant. "Obliged to decline" was plain enough; but his confused mind found some grains of comfort in the request of the firm to know what he wished done with his manuscript. They must, he reasoned, consider it of value, or they would not respond in that courteous manner. Still, he could not comprehend how they had had the asininity to "decline" it at all.

Were they unwilling to add another star to their galaxy?

Could they actually have read the tale?

A firm of their reputation, too!

When Roseleaf emerged from his temporary stupor it was into a state of great indignation. Why, the men were fools! He wished heartily he had never gone to them. They would yet see the day when, with tears in their eyes, they would regret their lack of judgment. His first act should be to go to their office and express his opinion of their stupidity, and then he would take his MSS. to some rival house. And never, never in the world--after he had become famous, and when every publisher on both sides of the Atlantic were besieging him--never, he said, should these ignorant fellows get a scrap of his writing, not even if they offered its weight in gold!

He was too excited for delay, and donning his hat, he took his way with all speed to Cutt & Slashem's office. At that instant he had more faith in his novel than ever. As he walked rapidly along he compared it with some of the stories issued by the firm that had rejected it, to the great disadvantage of the latter.

"I wish to see Mr. Cutt or Mr. Slashem," he said, imperiously, as he entered the counting room.

"Both are in," said the office boy, imperturbably. "Which will you have?"

"I will see them together."

Had they been tigers, fresh from an Indian jungle, it would have made no difference to him.

The boy asked for his card, vanished with it, returned and bade him follow. Up a flight of stairs they went, then to the left, then to the right, then across a little hall. A door with the name of the house and the additional word "Private" loomed before them.

"Come in!" was heard in response to the knock of the office boy.

Roseleaf entered, something slower than a cannon ball, and yet considerably faster than a snail. The two principal members of the firm were sitting together, with lighted cigars in their mouths, examining a lot of paper samples that lay upon a table. They did no more at first than glance up and nod, not having finished the business upon which they were engaged.

"Is it any better than the last?" asked Mr. Slashem, referring to the sample his partner was examining.

"It's just as good, at least," was the answer. "And an eighth of a cent a pound less. I think we had better order five hundred reams."

"Five hundred reams," repeated the other, slowly, making a memorandum in a little book that he carried. "And the other lot we'll wait about, eh? Paper is not very steady. It's gone off a sixteenth since Thursday."

This conversation only served to infuriate still more the visitor who stood waiting to pour out his wrath. Were these men wasting time over fractions of a cent in the price of stock, just after they had rejected one of the greatest romances of modern times!

With the precision of a duplex machine both partners finally looked up from the table at the young man.

"Mr. Shirley Roseleaf?" said Mr. Slashem, interrogatively, glancing at the card that the office boy had brought.

"Yes, sir!" was the sharp and disdainful reply.

"We need nothing in your line," interrupted Mr. Cutt. "I suppose Mr. Trimm has our other order well under way?"

The look of indignant protest that appeared in Roseleaf's face caused Mr. Slashem to speak.

"This is not Mr. Roseberg," he explained. "My partner took you for an agent of our bookbinder," he added.

The novelist thought his skin would burst.

"I am quite complimented," he said, in an icy tone. "Let me introduce myself. I am the author of 'Evelyn's Faith.'"

The partners consulted each other.

"The similarity of names confused me," said Mr. Cutt. "Is your book one that we have published?"

Saints and angels!

"It is one that was sent to you _for_ publication," replied Roseleaf, with much heat, "and has been returned this morning--_rejected_!"

"Ah!" said Mr. Cutt.

"We have nothing to do with that department," said Mr. Slashem, coming to the rescue. "You should see Mr. Gouger, on the second floor above; though if he has rejected your story a visit would be quite useless. He never decides a matter without sufficient reason."

"Oh, dear, no!" added Mr. Cutt, feeling again of the paper samples.

Shirley Roseleaf listened with wild incredulity.

"Do you mean to tell me," he said, "that you, the members of the firm of Cutt & Slashem, have rejected my story without even reading it?"

The partners glanced at each other again.

"We never read books," said Mr. Cutt.

"Never," said Mr. Slashem, kindly. "We have things much more important to attend to. We pay Mr. Gouger a large salary. Why, my young friend, there are probably a dozen manuscripts received at our office every week. If we were to try to _read_ them, who do you think would attend to the _essential_ points of our business?"

Roseleaf's contempt for the concern was increasing at lightning speed. He did not care to mince his words, for it could make no difference now.

"I should imagine that the selection of the books you are to print would be at least as important as the paper you are to use," he retorted.

Mr. Cutt looked at him in great astonishment.

"You are much mistaken," said he.

"Entirely mistaken," confirmed Mr. Slashem.

The author had no desire to remain longer, as it was evident he was losing his temper to no purpose. If it was Mr. Gouger who had rejected his work, it was Mr. Gouger that he must see.

Bowing with ironical grace to the examiners of printing paper, he took leave of them, and mounted to the sanctum of the man who he had been told was the arbiter of his fate. A girl with soiled hands pointed out the room, for there was nothing to indicate it upon the dingy panel of the door; and presently Roseleaf stood in the presence of the individual he believed at that moment his worst enemy.

There were two men in the room. One of them indicated with a motion of his hand that the other was the one wanted, and with a second motion that the caller might be seated. Mr. Gouger was partly hidden behind a desk, engaged in turning over a heap of manuscript, and it appeared from the manner of his companion that he did not wish to be disturbed.

Somewhat cooled down by this state of affairs, the young novelist took the chair indicated and waited several minutes.

"What d--d nonsense they are sending me these days!" exclaimed Mr. Gouger at last, thrusting the sheets he had been scanning back into the wrapper in which they had come, without, however, raising his eyes from his desk. "Out of a hundred stories I read, not three are fit to build a fire with! This thing is written by a girl who ought to take a term in a grammar school. She has no more

idea of syntax than a lapdog. Her father writes that he is willing to pay a reasonable sum to have it brought out. Why, Cutt & Slashem couldn't afford to put their imprint on that rot for fifty thousand dollars!"

He had finished saying this before he learned that a third person was in the room. Upon making this discovery he lowered his voice, as if regretting having exhibited too great warmth before a stranger. The novelist rose and handed him a card, and as Mr. Gouger glanced at the name a gleam of recognition lit up his face.

"I am glad to see you, Mr. Roseleaf," he said. "I had half a notion to ask you to call, when I felt obliged to send you that note yesterday. There are several things I would like to say to you. Archie, perhaps you would let us have the room for a few minutes."

The last remark was addressed familiarly to the man who occupied the third chair, and who looked so disheartened at the prospect of having to rise therefrom that Roseleaf hastened to express a hope that he would not do so on his account.

"Very well," said Mr. Gouger, abruptly. "You heard what I said about this copy I have just read, though it was not my intention that you should. I supposed I was talking only to Mr. Weil, who is not in the profession and does not expect to be. Now, let me say at once, Mr. Roseleaf, that your contribution is not open to any of the objections I have cited. You have evidently been well educated. Your English is pure and forcible. It is a real delight to read your pages. Every line shows the greatest care in construction. I did with your story what I have not done with another for a long time--I read it through. Why then did I reject it?"

The question was too great for the one most interested to answer, but in the glow of pleasure that the compliment brought he forgot for the moment his bitter feelings.

"Possibly," he suggested, "Cutt & Slashem have more novels on hand than they feel like producing at present."

"No," responded Mr. Gouger, disposing of that theory in one breath. "A house like ours would never reject a really desirable manuscript. If you will reflect that only one or two of this description are produced each year you will the more readily understand me. Your story has a cardinal fault for which no excellence of style or finish can compensate. Shall I tell you what it is, and before this gentleman?"

He indicated Mr. Weil as he spoke. Roseleaf's heart sank. For the first time he felt a deadly fear.

"Tell me, by all means," he responded, faintly.

Mr. Gouger's face bore its gentlest expression at that moment. He was taking valuable time, time that belonged to his employers, to say something that must temporarily disappoint, though in the end it might benefit his hearer.

"Let me repeat," he said, "that your work is well written, and that I have read it with the greatest interest. Its fault--an insuperable one--is that it lacks fidelity to nature. Mr. Roseleaf, I think I could gauge your past life with tolerable accuracy merely from what that manuscript reveals."

The novelist shook his head. There was not a line of autobiography in those pages, and he told his critic so.

"Oh, I understand," replied Mr. Gouger. "But this I have learned: Your life has been marvelously colorless. Yet, in spite of that, you have undertaken to write of things of which you know nothing, and about which, I may add, you have made very poor guesses."

Mr. Weil, leaning back in his chair, began to show a decided interest. Mr. Roseleaf, sitting upright, in an attitude of strained attention, inquired what Mr. Gouger meant.

"Well, for instance, this," responded the critic: "You attempt to depict the sensations of love, though you have never had a passion. Can you expect to know how it feels to hold a beautiful girl in your arms, when you never had one there? You put words of temptation into the mouth of your villain which no real scamp would think of using, for their only effect would be to alarm your heroine. You talk of a planned seduction as if it were part of an oratorio. And you make your hero so superlatively pure and sweet that no woman formed of flesh and blood could endure him for an hour."

The color mounted to Roseleaf's face. He felt that this criticism was not without foundation. But presently he rallied, and asked if it were necessary for a man to experience every sensation before he dared write about them.

"Do you suppose," he asked, desperately, "that Jules Verne ever traveled sixty thousand leagues under the sea or made a journey to the moon?"

Mr. Weil could not help uttering a little laugh. Mr. Gouger struck his hands together and clinched them.

"No," said he. "But he could have written neither of those wonderful tales without a knowledge of the sciences of which they treat."

"He has read, and I have read," responded Roseleaf. "What is the difference?"

"He has studied, and you have not," retorted the critic. "That makes all the difference in the world. He has a correct idea of the structure of the moon and what should be found in the unexplored caverns of the ocean; while you, in total ignorance, have attempted to deal in a science to which these are the merest bagatelles! You know as little of the tides that control the heart of a girl as you do of the personal history of the inhabitants of Jupiter! Your powers of description are good; those of invention feeble. Either throw yourself into a love affair, till you have learned it root and branch, or never again try to depict one."

Mr. Archie Weil smiled and nodded, as if he entirely agreed with the speaker.

"What a novel _I_ could make, my dear fellow!" he exclaimed, "if I only had the talent. I have had experiences enough, but I could no more write them out than I could fly."

"It is quite as well," was the response, "your women would all be Messalinas and fiction has too many now."

"Not _all_ of them, Lawrence," was the quick and meaning reply.

"In that case," said Gouger, "I wish heartily you could write. The world is famishing for a real love story, based on modern lines, brought up to date. I tell you, there has been nothing satisfactory in that line since Goethe's day."

Mr. Weil suggested Balzac and Sand.

"Why don't you include George William Reynolds?" inquired Gouger, with a sneer. "Neither of them wrote until they were depraved by contract with humanity. If we could get a young man of true literary talent to see life and write of it as he went along, what might we not secure? But I have no more time to spare, Mr. Roseleaf. I was sorry to be obliged to reject your story. Some day, when you have seen just a little of the world, begin again on the lines I have outlined, and come here with the result."

Quite dispirited, now that the last plank had slipped from under him, the novelist walked slowly down the stairs. He did not even ask for his manuscript. After what he had heard, it did not seem worth carrying to his lodgings. His plans were shipwrecked. Instead of the fame and fortune he had hoped for, he felt the most bitter disappointment. All his bright dreams had vanished.

A step behind him quicker than his own, made him aware that some one was following him, and presently a voice called his name. It was Mr. Archie Weil, who had put himself to unusual exertion, and required some seconds to recover his breath before he could speak further.

"I want you to come over to my hotel and have a little talk with me," he said. "Gouger has interested me in you immensely. I believe, as he says, that you have the making of a distinguished author, and I want to arrange a plan by which you can carry out his scheme."

Mr. Roseleaf stared doubtfully at his companion.

"What scheme?" he said, briefly.

"Why, of imparting to you that knowledge of the world which will enable you to draw truthful portraits. You have the art, he says, the talent, the capacity--whatever you choose to call it. All you lack is experience. Given that, you would make a reputation second to none. What can be plainer than that you should acquire the thing you need without delay?"

"The 'thing I need'?" repeated Roseleaf, dolefully.

Mr. Weil laughed, delightfully.

"Yes!" he explained. "What you need is a friend able to interest you, to begin with. Pardon me if I say I may be described by that phrase. Come to my hotel a little while and let us talk it over."

It was not an opportunity to be refused, in Roseleaf's depressed condition, and the two men walked together to the Hoffman House, where Mr. Weil at that time made his home.

CHAPTER II.

"WAS MY STORY TOO BOLD?"

"Well, Millie, your letter has come," said Mr. Wilton Fern, as he entered the parlor of his pleasant residence, situated about twenty miles from the limits of New York City. "Open it as quick as you can, and learn your fate."

His daughter started nervously from her seat near the window, where she had been spending the previous hour in speculations regarding the very missive that was now placed in her hands. She was a handsome girl, neither blonde nor brunette, with eyes of hazel gray and hair of that color that moderns call Titian red. She took the envelope that her father gave her, and though she wanted intensely to know the contents she hesitated to open it.

"Read it, Millie," smiled Mr. Fern. "Let us learn whether we have an authoress in our house who is destined to become famous."

But this remark made Miss Millicent less willing than before to open the letter in her father's presence. She slowly left the room without answering and did not break the seal of her communication till she was in the seclusion of her chamber.

And it was quite a while, even then, before she summoned the necessary courage. Some days previous she had sent a MSS. to the great publishing house of Cutt & Slashem. The writing had taken up the best of her time for a year. She had high hopes that it was destined to lay the foundation of an artistic success. Her plot was novel, not to say startling. It was entirely out of the conventional order. It would be certain to arouse talk and provoke comment, if it got into print; and to make sure that it _would_ get into print she had persuaded her father to write a little note, which she enclosed with the MSS., saying that he would pay a cash bonus, if the firm demanded it, to guarantee them against possible loss.

With this note in her mind, Miss Millicent had felt little doubt that her story would be accepted and printed. She only wondered how warmly they would praise her work. It was not enough to have them print it; she wanted something to justify her in saying to her father, "There, you see I was not wrong after all in thinking I could have a literary career!"

At last the envelope was removed, and the girl's astonished eyes lit upon this cold, dry statement:

"Messrs. Cutt & Slashem regret to be obliged to decline with thanks the MSS. of Miss M. Fern, and request to be informed what disposition she desires made of the same."

Millicent felt a ringing in her ears. Her hands grew clammy. A dull pain pressed on her forehead. She felt a faintness, a sinking at the heart. Was it possible she had read aright? Rejected, in this cruel way, without even a reference to her father's offer! It was atrocious, and, girl-like, she burst into a spasm of weeping.

How could she ever face her father? The sacrifices she had made came back to her, sacrifices of which she had thought little at the time, but which now seemed gigantic. There had been nights when she had not gone to bed till three, other nights when she had been too full of her subject to sleep and had risen in the small hours to finish some particularly interesting chapter. Twelve hundred pages there were in all, note size, in her large, round, almost masculine hand. And this time was all lost! She had mistaken her vocation. The greatest publishing house in the country had decided against her.

Gradually she dried her eyes. It would do no good to weep. She read the curt answer that had come in the mail, a dozen times. Why could not the firm have sent her a reason, an excuse that meant something? She wanted to know wherein her fault lay. It might be possible to correct it. Perhaps the state of business was to blame. The more she thought, the more determined she grew to investigate this strange affair, and within an hour she had donned her street clothes and started, without saying anything to the rest of the household of her intention, for the office of Cutt & Slashem in the city.

She knew that each large concern had one or more "readers," on whose judgment they relied in such matters. She, therefore, paused only long enough at the counting-room to get directed to Mr. Gouger. Her knock on the critic's door brought forth a loud "Come in," and as she entered she saw two men standing with hats in their hand, as if about to take their departure.

"I beg your pardon," she said, "but I wish to see Mr. Gouger."

"That is my name," responded one of the men, stepping forward.

"I am Miss Fern."

Mr. Gouger did not seem very glad to hear it. The hour of one had just struck, and he was about to go to his lunch. He recognized the girl's name, as that of the author of the MSS. he had criticized so severely to his friend, Weil, who was, by-the-way, the third person in the room at this moment. Had she sent up her card, as is usual with women, he would have avoided seeing her at any hazard.

Mr. Weil took a long survey of the young lady, and then retired to the vicinity of the front windows. He pretended to interest himself in the rush of traffic that was going on in the street below, but he missed nothing of what was said, and stole from time to time a glance at his two companions, particularly the younger one.

"A mighty pretty girl," was his mental comment. "I hope Lawrence isn't going to be nasty with her."

Mr. Gouger motioned Miss Fern rather stiffly to a seat.

"I do not wish to detain you," she said, with feminine inconsistency, as she accepted it. "I only want to know, if you will be so kind as to tell me, what is the trouble with my story."

The critic was pleased at one thing. Miss Fern's voice was reasonably clear. She had finished her weeping at home. There was to be no scene, something he dreaded, and in the course of his connection with this house he had experienced scores of them. He inspected his caller critically in the few seconds that elapsed while she was asking this question, and when she paused he decided to answer her with as much of the truth as he dared use.

"The fact is," he began, "a firm like ours is unable to use more than one novel out of fifty that is submitted to it. Of our friends who send us manuscripts, the vast majority must, therefore, be disappointed. Now, your story--shall I be frank?"

"By all means," answered Miss Fern.

"Your story, though written with spirit and power, needs a great deal of revision from a--from a rhetorical standpoint. It is, in fact, carelessly put together. That is a cardinal fault in a literary production, and one for which no amount of talent, or even of genius, can compensate."

The girl listened with deep interest. She tried to think where the blemishes alluded to could be, for she had read the story twenty times. To say nothing of several girl friends, who had listened with evident wonder and delight, to various parts of the tale, as it progressed.

"If that is true," answered Miss Fern, slowly--, "could not the trouble be remedied by sending the MSS. to some very competent person and having the errors made right?"

Mr. Gouger smiled.

"Hardly," he said. "A novel is like a painting. The _ensemble_--do you understand?--is the thing. Can you conceive a painting being 'done over'? Your book would lose its quality if subjected to that process."

A look of discouragement crossed the features of the young woman.

"Of course, you know best," she stammered. "What would you advise me--try again?"

Mr. Gouger raised both his hands.

"It is difficult to say, in such a case," he replied. "But--if you want my best opinion--"

"That is just what I want," said the girl, with ill-concealed impatience.

"You are not dependent upon your exertions, I suppose, for a living?"

Millicent shook her head, almost sorry at the moment that she could not reply in the affirmative.

"Then--I should give up the idea of being an authoress."

This was very unpalatable medicine, and the critic realized it as he looked at the sombre face before him.

"Is your rejection of my story based at all," asked Miss Fern, after a pause, "on the--boldness of its subject?"

Mr. Gouger smiled again.

"We publish the works of Hall Caine and George Moore," he said. "I should not consider your story overbold, if there was nothing else against it. It is a wonder to me, and always will be, why such young girls as you choose _risque_ themes, but if the work is well done the public will pay for it."

There was a slight blush on Miss Fern's face, partly at the insinuation and partly at the adverse criticism that had crept thoughtlessly into the sentence.

"For my part," she explained, "I wanted to write something that would attract attention--that would put my name prominently before the public and keep it there. The girls I read it to thought the scenes just lovely, though some said perhaps their mothers would not feel that way. And I told them that the mothers of to-day were very old-fashioned, and that the public taste was changing rapidly. If the story is too bold, there are things I could cut out of it, but if you say that would make no difference, I would rather let them stand. I intend to try some other concern before I give up."

Mr. Archie Weil had abandoned all pretence of looking out the window. He stood with his eyes fastened on the pretty girl, as she made these statements in such a matter-of-fact way. He wondered what the dickens the story was about, and made up his mind that he would try to get possession of it.

"All the same," responded Mr. Gouger, who had apparently forgotten his lunch in his growing interest in the conversation, "I don't see where girls like you obtain such an intimate knowledge of things. You are not over twenty--excuse me, I am old enough to tell you this without offence. It is not you alone, but a hundred others who have made me ask myself this question. As soon as the modern girl gets a bottle of ink and a pen and begins to let her thoughts flow over paper, it transpires that she knows everything--more than everything, almost. Why, I was twenty-five before I was as wise as the heroine of sixteen, in this story of yours!"

Miss Fern reddened again, all the more because she had glanced up and encountered the bright eyes of Mr. Weil fixed upon her.

"Why, Archie," pursued the literary man--he turned toward Mr. Weil--"you remember Lelia Dante, you have seen her here. Five or six years ago I got a letter from that young girl's mother asking me to come to their residence and hear a story she had written. It was her first one, and the child was not a day over seventeen. I couldn't believe it when she came into the room, with her hair tumbled about her shoulders, and began to read to me the first chapter of 'Zaros.' 'Did _she_ write that?' I asked her mother, incredulously. 'Certainly,' she replied. 'Without aid from any one?' 'Absolutely alone.' My hair stood on end. I could not keep it down for the next week with a brush. You know the story. We printed it, and it sold well, and that is all that C. & S. cared about it; but I never understood how that infant could conceive it. No more than I can understand your ability to write this story of yours, Miss Fern," he added, pointedly.

The young woman bridled a little.

"It does not matter much, if you are not going to print it," she said, raising her eyes to his.

He bowed low to express whatever apology might be necessary.

"I would have accepted it if I could," he said. "My entire life is spent in reading manuscripts in the hope of discovering one that will make a hit with the public to whom we cater. When successful I am as pleased as a South African who fishes a diamond of the first water out of the mine. Your story, Miss Fern, shows decided talent. You have a greater knowledge of some of the important things of life, I will wager, than your grandmother had at eighty, if she lived so long. As I am obliged to go now, let me add, without mincing matters, that you are very deficient in English grammar, and that nothing you can write will be acceptable to any first-class house until that fault is remedied. Are you ready, Archie?"

Mr. Weil felt indignant. He could not have spoken to any girl as pretty as this one in such language, and he thought it quite inexcusable on the part of his friend to do so. Mr. Gouger, though feeling that it was best to use little circumlocution, had not meant to wound his caller. But her countenance showed that he _had_ wounded her, and the natural gallantry of his younger companion came to the rescue.

"I am not ready yet," said Mr. Weil, telegraphing at the same time a series of signals with his eyes. "I want a few minutes' talk with Miss Fern, if you will introduce me. I think I can say something she will like to hear."

Mr. Gouger, who now stood in such a position that Miss Fern could not see him, shook his head to imply that he did not fancy this arrangement; but he ended by saying, "Very well." He then abruptly made the presentation, put on his hat, said good-by, and vanished.

Miss Millicent, who had risen, turned with an air of puzzled inquiry toward Mr. Weil.

"Be seated again, for a moment," he said, politely. "I want your permission to read your story."

"Why, I don't know," she answered. "Are you one of the employes of Cutt & Slashem?"

He smilingly denied the imputation.

"I have not that felicity," he added, "but I am much interested in things literary, and have a rather wide acquaintance in this line of business. If I could be allowed to read your MSS. perhaps I should form a milder opinion of its faults than my unbending friend. And in that case a word from me, to another house, would certainly do you no harm."

A brighter light came into Miss Millicent's eyes.

"I shall be only too glad to have you read it," she answered. "It is hard to believe that I have wasted almost a year in something entirely worthless. You may take it with pleasure."

Mr. Weil went to Mr. Gouger's desk, from which he soon came with the parcel in question. He untied the string and for a moment his gaze rested on the handwriting.

"Do you live far from here?" he began; and then added, as he noticed the address on an enclosed card, "Ah, I see! At Midlands."

She explained herself rather more to him, giving the full address of her father, and some particulars about the manner in which she had been drawn into attempting literary work. He listened intently, all the time engaged in rapid thought.

"The best way for me to get a thoroughly correct impression of this novel," he said, when she came to a pause, "is to hear you read it aloud. In that manner," he added, as he saw that she was about to interrupt, "a hundred meanings would come to the surface that a mere inspection of the pages might fail to show. Beside, there would be an opportunity for discussion. If convenient to you I would gladly come to your residence for this purpose."

The eyes of the young girl brightened. She was greatly pleased at the idea and said so without delay.

"Very well," said Mr. Weil, more than delighted with the success of his experiment. "To-day is Tuesday; shall I come for the first time, say, Thursday evening?"

"That would suit me perfectly; or to-morrow, if you wish. I shall put aside everything and have my time free for you."

Mr. Weil nodded.

"Let it be Thursday then. And the hour--shall we call it eight?"

The time was promptly agreed to.

"In the meantime, I will take the MSS. and look it over, to form a general idea of the plot. Here is my card. By-the-way, you will of course arrange it so that we shall not be interrupted during our conference. It disturbs anything of that kind to have people coming in and out. We want to be entirely alone so as to give our full attention to the work in hand."

Miss Fern smilingly acquiesced, saying that it was exactly what she would wish.

"And do you think there may be hope for it yet--that poor little manuscript?" she asked, as she stood by the door ready to take her departure.

"That is a question I can hardly answer," he replied. "I shall be better able to tell you in a week or two, I trust."

She lingered, with her hand on the door knob.

"My father is willing to take all the financial risks," she said. "That ought to make a difference, don't you think so?"

"It would, with many houses," he admitted. "I am glad to know these things. Thursday, then, Miss--Miss Fern."

He wanted to call her "Millicent," for he had read the name on the package he still held in his hand; but on the whole he concluded that this would be a little premature.

CHAPTER III.

"HER FEET WERE PINK."

When Miss Millicent Fern entered the office of Lawrence Gouger, as detailed in the preceding chapter, it will be remembered that she found that gentleman and his friend, Archie Weil, with their hats in their hands. The fact was that Mr. Weil had but just entered the room, and that Mr. Gouger had accepted an invitation to take lunch with him, an arrangement that was by no means an infrequent one between them. The entrance of Miss Fern, and the subsequent proceedings, compelled the literary critic to go out alone, as has been seen. When he returned he found Mr. Weil still there.

"Haven't you been to lunch yet!" exclaimed Mr. Gouger.

"I have not been out of this office," was the reply, "and all appetite for anything to eat has left me. Lawrence, that is one of the most interesting girls I ever met."

Mr. Gouger pursed up his lips, and uttered an impatient, "Pah!" He then remarked that Mr. Weil had a habit of finding such a quality in the latest women of his acquaintance.

"What does she amount to?" he asked. "An overgrown schoolgirl, who did not half learn her lessons. Read that MSS. she left here, and get disillusionized in short order. Why, she doesn't even know how to spell, and her periods and commas are in a hopeless tangle."

His companion eyed him quizzically.

"Are periods and commas, even a correct spelling of the English language, the only things you can see in a bright, handsome girl?" he demanded. "For shame, Lawrence! You are a dried-up old mummy. Your senses are numb. A lively wind will come in at the keyhole some day and blow you out of that chimney."

Mr. Gouger heaved a sigh, as if to say that discussion with such a nonsensical fellow was useless, and took his seat at his desk, where an unfinished pile of MSS. awaited his reading.

"She's given me leave to take her story home," said Mr. Weil, with a mischievous expression.

The critic stared at his friend.

"Given it to you?" he repeated. "How did that happen?"

"I asked her for it, naturally. You were so severe on the poor child, that I couldn't help putting in a cheering word. We talked of the whole business, and she was willing I should see if my opinion agreed with yours."

"_Your_ opinion!" echoed Gouger, testily. "What is that worth? But take the stuff, if you want it, and when you are done, send it to her; it will make less rubbish in this confounded hole. One thing I'll tell you, though, in advance. You'll never be able to make sense of it, unless you get some one to straighten it out."

"That's all right," replied the other. "After I have read it through, I am going to Miss Fern's house, where she will read it to me."

Mr. Gouger started from his chair.

"You don't mean that!" he exclaimed.

"But I do. She asked me, and I'm going. I understand that it's a rather bold tale, and I can conceive nothing more entertaining than to hear that kind of thing from the red lips of such a pretty piece of flesh and blood as has just left here."

There was an uneasy expression on the face of the critic as he heard these words. He liked Weil, although they were as different in their natures as two men could well be. He wanted to please him, but the aspect of this affair was not agreeable.

"Look here, Archie," he said, earnestly, "there are some things that I can't permit, you know. My office must not be made a starting-place for one of your lawless adventures. You met Miss Fern here. Now, I protest against your going to her house, pretending that you are interested in that novel, when your real purpose is of a much more questionable kind."

Mr. Weil put on the air of one whose feelings are lacerated by an unjust suspicion.

"My dear Lawrence--" he began.

"That's all right," growled the critic. "I may or may not be your 'dear Lawrence,' but I know you like--like a book," he added, hitting by accident on a very excusable simile. "You are an old dog that is not likely to learn new tricks. I shall send this MSS. back to Miss Fern, myself, enclosing a letter warning her to have nothing to do with you."

A laugh escaped the lips of Archie Weil at this proposition.

"If you knew the feminine mind half as well as you do modern literature," he answered, "you would see how little that would avail. I have met Miss Fern and made a distinctly favorable impression. Her address is in my pocket, and I have received a pressing invitation to call. If you choose to send the MSS. by another messenger you will relieve me of the task of carrying a bundle, but you will accomplish nothing more."

Mr. Gouger's mouth opened in astonishment at the evident advantage which his friend had gained in so short a time.

"You must have convinced her that your literary opinions are of value," he said, presently. "If I write that you are a charletan and entirely unworthy of attention, what will happen then?"

The smiling gentleman opposite crossed his hands over his left knee, and did not delay his answer.

"I will tell you," he said. "In the same mail she will receive a letter from me, warning her that a certain party, who has given an adverse judgment on her writings, may attempt to influence her against others more likely to decide in her favor. She will be told that, having rejected a book, this certain party does not wish any one else to print it. Send the severest note you can construct, Lawrence. I have few talents, but I know how to write letters."

The critic could hardly believe that fate had thrown so many cords around his neck in the brief space of one hour, but the more he thought the more he became convinced that his best course was to shut his eyes.

"Well, gang your gait," he said, after a long pause, during which the look of triumph deepened on his companion's face. "You will have to answer for your own sins. But I'll tell you one thing, that may save your time. Women who write racy novels are almost without exception remarkably correct in their own lives."

Mr. Weil inquired if his friend was certain of this, and there was a suspicion of disappointment in his tone.

"Absolutely," said Mr. Gouger, refreshing his memory. "I can think of a dozen instances to prove the point. There is Lelia Dante, for instance, who writes like a--like a--well, you know how she writes. She sticks to her mother's apron strings like a four-year-old child. They never are seen apart, I am told. Then there is Mrs. Helen Walker Wilbur, the poetess. We have a volume of her verse that is positively combustible from its own heat. The sheets had to be run off the press soaked in water to keep them from igniting. The room was full of steam all the time the work was going on. Warm! I should say so! Now, that woman is vain, and she dresses foolishly, and she does odd things for the sake of being talked about--but nobody questions her loyalty to her husband. You would think by some of her poems that an East Indian regiment would not suffice for her, and yet she is the straightest wife on Manhattan Island. Oh, I know so many cases. You remember that girl who wrote, 'Love's Extremities,' a work as passionate as Sappho. She is a little Quaker-like maiden,[A] who dresses and talks like a sister of one of the Episcopal guilds. These women are on fire at the brain only. They would repel a physical advance with more indignation than those endowed with less esthetic perceptions. So, see Miss Fern as much as you like. Should you attempt anything improper you will prove the truth of my assertions."

[Footnote A: Now dead, alas!--A. R.]

Mr. Weil changed the knee he had been nursing, but the quiet smile did not leave his countenance.

"What an inconsistent fellow you are, Lawrence," he said. "I could convict you of a hundred errors of logic. Do you remember telling Mr. Roseleaf that a man should have a passion before he attempts to depict one."

"And I say so still," retorted Gouger. "_You_ don't call the ravings of these poetesses and female novelists real life, do you? _You_ know the actual lover isn't content with kissing the hair and the feet of his divinity! There is more about women's _feet_ in these poems and novels than all the rest of their anatomy put together. And what is a woman's foot? Did you ever see one that was pretty--that you wanted to put to your lips?"

"Yes," interrupted Archie, dreamily, "once. At Capri. She was fifteen. Her feet were pink, like a shell. She was walking along the shore in the early evening."

"With the dirt of the soil on them!" exclaimed Mr. Gouger, in disgust.

"No, she had just emerged from her bath. The sand there was clean as a carpet, cleaner, in fact. Gods! They were exquisite!"

The critic uttered an exclamation.

"I waste time talking to you," he said, sharply. "You are like the rest of the imaginative crowd. It is a pity you were not gifted with the divine afflatus, that you could have added your volumes to the nonsense they print."

"And which you are always glad to get," interpolated Mr. Weil.

"Because it will sell. Cutt & Slashem are in this business to make money, and my thoughts must be directed to the saleable quality of the manuscripts submitted. If _I_ was running the concern, though, I would touch the mooney, maundering mess. It makes my flesh creep, sometimes, to read it."

Archie Weil uttered another of his winsome laughs.

"How would you like to be a serpent," he asked, "and have your flesh creep all the time? But before we dismiss this matter of Miss Fern, I want you to clear your mind, if you can, of the haunting suspicions you always have when a woman is concerned. You know there are concerns in the city who would print her book, with a proper amount paid down, if it had neither sense, syntax nor orthography. If she wants it fixed up, I can find tailors to help her out; and if her papa wants it on the market, why shouldn't he be able to get it there? Now, let us talk a little about Roseleaf."

Mr. Gouger brightened at the change of subject. His interest in Mr. Roseleaf was genuine, and he had already learned that Archie had formed a sort of copartnership with the novelist, in the hope of making his future work a success. While the critic could not be said to have any real faith in the arrangement, it certainly interested him.

"What strange freak will you take to next?" he asked. "And do you really expect to make a novelist out of that young man?"

Mr. Weil's eyes had a twinkle in them.

"Didn't you say, yourself, that it could be done?" he inquired. "If I have made any mistake in my investment, I shall charge the loss to you."

The critic reflected a minute.

"I'm not so certain it _can't_ be done," he said. "But that's quite different from investing money in it, as you are doing. A man wants pretty near a certainty before he puts up the stuff."

"You greedy fellow!" exclaimed Weil. "Will you never think of anything but gain? I have to spend about so much money every year, in a continual attempt to amuse myself, and it might as well be this way as another. I have a document, signed and solemnly sealed, by which I am to back him against the field in the interest of romantic and realistic literature, and in return he is to give me a third of the net profits of his writings. I don't know that I have done so badly. Perhaps you may live to see Cutt & Slashem pay us a handsome sum in royalties."

Mr. Gouger looked oddly at his friend, whose face was perfectly serious.

"What are you going to begin with?" he asked.

"Love, of course. It is the A B C, as well as the X Y Z of the whole business."

"What kind of love?"

"The best that can be got," replied Weil, now laughing in spite of himself. "The very finest quality in the market. Oh, we shall do this up brown, I tell you."

"What have you done so far?" asked Gouger.

"You want to know it all, eh?" responded Mr. Weil. "I don't think I am justified in letting you too deeply into our secrets. However, you are too honorable to betray us, and so here goes: I have instructed my protege that he must fall violently under the tender passion before next Saturday night."

"With a lady whom you have selected, of course?"

"By no means. He must catch his own sweethearts."

Mr. Gouger played with his watchchain.

"And this is Tuesday," he commented. "Do you think he will succeed?"

"He must," laughed Weil. "It's like the case of the boy who was digging out the woodchuck. 'The minister's coming to dinner.'"

"You might at least have got an introduction for him," said Gouger, reflectively.

"Not I. There's nothing in our agreement that puts such a task on me. Besides, there's no romance in an introduction. He would write a story as prosy as one of Henry James' if he started off like that."

Mr. Gouger nodded his head slowly.

"That would be something to avoid at all hazards," he assented.

And at this juncture, to the surprise of both the parties to this conversation, the young man of whom they were speaking entered the room.

"I was telling Mr. Gouger of our agreement," said Mr. Weil, as soon as the greetings were over. "How do you get along? Have you discovered your heroine yet?"

Mr. Roseleaf answered, with an air of timidity, in the negative.

"I don't quite know where to find one," he said.

Mr. Weil spread out his arms to their fullest capacity.

"There are thirty millions of them in the United States alone," he exclaimed. "Out of that number you ought to find a few whom you can study. What a pity that _I_ cannot write! I would go out of that door and in ten minutes I would have a subject ready for vivisection."

The younger man raised his eyebrows slightly.

"But, that kind of a woman--would be what you would want--the kind that would let you talk to her on a mere street acquaintance!"

Mr. Weil leaned back in his chair and stretched his legs.

"Oh, yes," he said. "She would do for a beginning. Don't imagine that none of these easy going girls are worth the attention of a novelist. Sometimes they are vastly more interesting than the bread and butter product of the drawing rooms. It won't do, in your profession, to ignore any sort of human being."

Roseleaf breathed a sigh as soft as his name.

"You were right, Mr. Gouger," he said, turning to that gentleman. "I do not know anything. I have judged by appearances, and I now see that truth cannot be learned in that way."

"All the better!" broke in Archie. "The surest progress is made by the man who has learned his deficiencies. You remember the hare and the tortoise. I have read somewhere that the race is not always to the swift. You must treat your fellow men and women as if you had just arrived on this earth from the planet Mars. You must dig through the strata of conventionality to the virgin soil beneath.

The great human passions are lust and avarice, though they take a thousand forms, in many of which they have more polite names. For instance, the former, when kept within polite boundaries, is usually known as Love. As Avarice makes but a sorry theme for the romantic writer, Love is the subject that must principally claim your attention. All the world loves a lover, while the miser is despised even by those who cringe beneath the power of his gold. Study the women, my lad, and when you know them thoroughly begin your great novel in earnest."

Roseleaf listened with rapt attention.

"And the men?" he asked.

"The men," was the quick reply, "are too transparent to require study. It is the women, with their ten million tricks to cajole and wheedle us, that afford the best field for your efforts."

Mr. Gouger, who had never been known to take so much time from his work during business hours, tried to begin his reading, but without success. When at his usual occupation he would not have been disturbed by the conversation of a room full of people, so preoccupied was he with what he had to do; but on this occasion he was too much entertained with his companions to do anything but hear them through.

"Is there no such thing as unselfish love--in a woman--love that sacrifices itself for its object?" asked Roseleaf, with a trace of anxiety in his tone.

"M----m, possibly," drawled Mr. Weil. "A female animal with young sometimes evinces the possession of that sort of thing, and women may have touches of it on occasions. That will be a good point for you to remember when you are deeper in your investigations. However, I ought not to fill your head with ideas of my own. I think what we most desire in our friend," he added, turning to the critic, "is complete originality."

The young man shifted his feet nervously.

"Pardon me," he said, "would it not be well to talk with people and learn their impressions? Then I can compare these with my own experiences, when they come. You would not send a blind man out on the street unled."

Archie Weil laughed deliciously.

"You are ingenious, when you should only be ingenuous," he replied. "You do not act at all like the young man from Mars that I have in mind. Perhaps, nevertheless, you are not wholly wrong, for even my traveler from that planet might have to ask his way to the nearest town. Supposing you had just reached the earth, and had met me with a thousand questions. What could I answer that would be of any use?"

Mr. Roseleaf reflected a moment.

"You could tell me your idea of a perfect woman," he suggested.

"Well, I will," said Weil, glancing meaningly at Mr. Gouger. "The perfect woman is about nineteen years of age. She is neither very light nor very dark. Her eyes are hazel, with a touch of gray in them. She measures, say, five feet, four inches in height, and--about--twenty-two inches around the waist. She has a plump arm, not too fleshy, a well-made leg, a head set on her shoulders with enough neck to give it freedom and grace of movement, but not sufficient to warrant comparison with a swan, or even a goose. Her hands match her feet, being not too slender nor too dainty. Her hips are medium, but not bulging. She weighs in the vicinity of a hundred and twenty-five pounds. And her hair--there is but one color for a woman's hair--is Titian red."

The young man had taken out his note-book and rapidly sketched this list of attractions.

"Every woman cannot have Titian hair," remarked Mr. Gouger. "Would you condemn one with all the other attributes on account of missing that?"

"I would, decidedly," was the reply, "when it is obtained so easily. I think it only costs two dollars a bottle, for the finest shade. Have you written it all down, Mr. Roseleaf?"

The young man ran over his notes.

"I have it--all but the hair," he said. "Of course I could not forget that."

"Very well. And this hair must be long enough, but not too long, remember, for everything unduly accentuated spoils a woman. It should hang about five inches below the waist, when unfastened, and be thick enough to make a noticeable coil. There should be sufficient to hide her face and her lover's when he takes her in his arms."

Mr. Roseleaf started slightly.

"Then she should have a lover?" he remarked, curiously.

"Undoubtedly. Else why the hair and the arms, and the five feet four! It is a woman's business to be loved and to make herself lovable. When you have found this woman, if she has no lover, you will be expected to officiate in that capacity. If she has one, you must supplant him as soon as possible. And when you have fallen desperately, ravingly in love with such a creature, you will not have to come to me for further advice."

The young man surveyed the speaker with the utmost gravity.

"Have _you_ ever been in love?" he inquired.

"Never."

"Why?"

"It was not necessary; _I_ did not intend to write novels," said Archie, with a laugh. "But, come, we have bothered Lawrence enough. Let us go."

He took the package containing Miss Fern's story, and sauntered out, paying no attention to the peculiar glances that his friend, the critic, threw at him as he was leaving.

CHAPTER IV.

WITH TITIAN TRESSES.

Mr. Weil deciphered the MSS. of Miss Fern with some difficulty. Not that the handwriting was particularly illegible, though it did not in the least resemble copperplate engraving; but, as Mr. Gouger had intimated, the sentences were so badly constructed, and the punctuation so different from that prescribed by the usual authorities, that he was continually obliged to go back over his tracks and hunt for meanings. Nevertheless, within an hour from the time when he sat down in his room at the Hoffman House and opened the package he had brought, he had to confess himself deeply interested.

Miss Fern had conceived some entertaining characters, and some very unconventional situations. Her people were virile; her hero was strong if not always grammatical; her heroine did and said things not common in real life, and yet that were quite reasonable when her peculiar nature and environment were considered.

Archie paused once in awhile to wonder how much of all this record was within the direct knowledge of the young authoress; which expressions conveyed her own ideas and which sentiments she would personally endorse. Gouger might be right as to the exceeding purity of most of the ladies who dealt in eroticism, but in this especial case Mr. Weil meant to make an investigation on his own account before he accepted as a universal rule the one his friend had laid down.

He did not go to sleep that night until he had finished his story. Had it been arranged by a competent hand he could have read it in four hours, but as it was he consumed eight in the work. With all its faults, he liked it. There was something breezy about it, and it had a theme that he did not remember had been treated exactly in the same way before. Though, as he himself had said, without much talent for composition, Archie had read a great many books. It is no proof because a person cannot write that he would make a poor critic. Mr. Weil might almost have filled Lawrence Gouger's place at Cutt & Slashem's. He had written fugitive pieces in his time for the papers, in reference to his travels, which had been extensive, and had even contributed occasional book reviews to the magazines. His connection with Gouger enabled him to keep in touch with what was going on in the literary world, and the dozens of new volumes which passed through that office were always at his disposal.

"She's not a fool, by any means," he remarked to himself, when he put down the last sheet of Miss Fern's work. "A fellow who understood his business might put that into such shape that it would be worth using. I mean to find some one who can do it, and suggest the idea to her, when I get to that stage in this affair. Let me see, who do I know that could undertake it?"

He had begun to undress, and was in the act of taking off his collar as he spoke. His mind ran over a list of struggling literary men. Something seemed the matter with most of them. There was Hamlin, but he would be too exacting, and would want to suggest alterations in the story itself, which would never do. There was Insley, whose last three books had been flat failures, and for whom Cutt & Slashem had positively refused to print anything more; but Insley had gone into the country for the summer and nobody knew his address. Then there was--

"_Roseleaf!_"

Archie received this thought like an inspiration. He threw his cravat on the bureau and began tugging at his shoestrings to the imminent danger of getting them into hard knots that no one could unravel. Roseleaf! Why not? The boy would do almost anything he suggested, so great was his confidence that a road to literary preferment could be staked out over that path. Roseleaf would not undertake the work for the sake of pecuniary compensation, but the thing could be presented to him in quite another light. In Miss Fern's story there were living, breathing men and women. In his own there were beautifully drawn marionettes. He could be made to see that the study of the young lady's method was worth his while. And then!

Mr. Weil's shoes lay on the floor, in the disorder of a bachelor who had never in his life taken pains to put anything in the place where it really belonged. He took out the studs of his shirt, pulled that garment over his head, and then sat for some minutes wrapped in active thought.

"They must be introduced to each other!" he exclaimed, at last. "Between them they have every qualification for success; apart they are like the separated wheels of a watch. There is Shirley, with a style so sweetly subtle, a grace so perfect, every line a gem; and with it all not a sign of human emotion. There is Millicent, full of plot and daring and breathing characters, and bold conceptions, and no more able to write good English than an Esquimaux squaw. I have both these interesting persons on my hands, and I must combine them, for their mutual good.

"I wonder what Gouger will say when I unfold my plan. Perhaps I had best not tell him. He actually came near threatening, to-day, to send a line to Miss Fern, warning her against me. He wouldn't have done it, though. Lawrence has a bark that is worse than his bite by a great deal. Yes, I'll bring these young folks together. I'll take them as Hermann does the rabbits, and press them gently but firmly into one. And then sha'n't we get a combination! And won't Mr. Lawrence Gouger hug himself when the product of their joint endeavor comes to him for a reading!"

The muser finished disrobing and donned his night robes, but it was a long time before he felt like slumber. He could think of nothing but his scheme. As he revolved it over in his mind, it took many new forms. At first Roseleaf was to be asked to rewrite the story that Miss Fern had offered Cutt & Slashem. And afterwards there must be an entirely new novel, conceived together and worked out slowly, using the best of what was brightest in both of them.

The last idea Mr. Weil had before he relapsed into unconsciousness contained two novels, worked out at the same time. Roseleaf was all right, if he could only get a glimpse of realism into his work. Miss Fern would have no trouble if her ideas could find a garb that suited them.

There would be a way to make them of service to each other, and the time to cross a bridge is always when you come to it. So thought Archie Weil, as he fell asleep.

In the morning he laughed to think of the description he had given to Shirley, in his offhand way, of "the perfect woman." It was a faithful list of Miss Millicent's charms, so far as they were apparent to him. Shirley had noted them down with great carefulness, and would be sure to notice how fully the authoress met the ideal he now had in mind. It only remained for the schemer to say something to Miss Fern that would suggest Roseleaf to her, whenever they were made acquainted.

It must be plain to the reader that Mr. Weil's principal intention in this whole matter was to dispose of the _ennui_ which idleness brings even to its most adoring devotees. He had a fair fortune, accumulated by a father who had denied himself every luxury to amass it. Drifting to New York, he had found the vicinity of the Hoffman House very agreeable, and his companions, with the exception of Mr. Gouger, were of about as light views of life as himself. The critic was one of those strange exceptions with which most of us come in contact, where persons of entirely opposite tastes and inclinations become attached friends.

Breakfast was served so late to Mr. Weil that he had not finished that repast when the young novelist made his appearance. Seating himself on the side of the table that faced his friend, Mr. Roseleaf responded to the latter's inquiries in regard to his health

by saying that he was quite well. Indeed, he looked it. His eye was bright, his cheek rosy. His attire showed just enough of a negligent quality to be attractive. There was an air about him such as is often associated with an artist of the pencil and brush.

"Never better in health," he said, "but very anxious to begin something definite in the way of work."

Mr. Weil smiled his most affable smile.

"What did I tell you to do, first?" he asked, playfully.

"To fall in love."

"Which you have not yet done!"

The young man shook his head.

"Good Heavens! And you have lost more than a week!"

Roseleaf colored more than ever.

"Isn't there something else--that I could--begin on?" he asked, humbly.

"I don't know of anything. Love is the alphabet of the novelist. You'd best go straight. Aren't there any eligible young women at your lodging house?"

The younger man thought a moment.

"No; only the chambermaid."

Mr. Weil sipped his coffee with a wise expression.

"It may come to that," he said, putting down the cup, "but we'll hope not. We will hope not. What's the matter with Central Park? There are five hundred nice girls there every afternoon."

"But I don't know them," said Roseleaf, desperately. "And--I have been there. Yesterday one of them looked at me and smiled. I walked toward her, and she slackened her speed. When I came within a few feet she almost stopped. Then--I could think of nothing to say to her, and I walked on, looking in the other direction."

Several breakfasters in the vicinity turned their heads to note the couple at the table, from which a laugh that could be heard all over the room came musically.

"Why didn't you say 'Good-morning?'"

"Yes! And she might have said 'Good-morning.' And then it would be my turn, and what could I have done?"

Mr. Weil folded up his napkin and laid it by his plate.

"You coward," he replied, affably, "you could have done a thousand things. You could have remarked that the day was fair, or that you wondered if it would rain. And you could have asked her to stroll over to a restaurant and take a little refreshment. Once opposite to her, the rest would have come fast enough."

The novelist took out a handkerchief and wiped the perspiration from his forehead. It all seemed very easy the way Archie described it, but he was sure it would be very different in practice. How could he know, he demanded, that the young lady would go to the restaurant with him? She might have declined, and then he would have been in a worse position than ever.

"Declined!" echoed Archie. "Declined a lunch? Declined ice cream? Declined champagne frappe! Well, you _are_ ignorant of the sex. My dear boy, it is evident that I shall have to introduce you to the leading lady of your company, and if you will be patient for a very few days, I hope to be able to do so."

Rousing himself with a show of genuine interest, Roseleaf inquired for further particulars.

"Listen," replied the other. "I expect, to-morrow evening, to spend a few hours in the company of one of the most charming members of her sex. She, like you, has an ambition to become a successful writer. Like you, also, she lacks some of the prime

qualities that are needed for that end. It happens, however, that the things wanting are entirely different in each of your cases--that you will, if you choose, be able to supplement and perfect each other. I shall tell her that I know a young man of literary taste who will give her advice on the points in which she is deficient. With such an opening you will be at once on Easy street, and if you cannot fall in love within forty-eight hours, I shall regard you as a case too hopeless to merit further attention at my hands."

The young man's cheek glowed with pleasure.

"That is more like it," he said. "When do you think I shall be able to meet this young lady?"

"Within a week or two, at the latest. I must sound her before I trust you with her, for she is nearly as much a stranger to me, so far, as to you. Of course there is no objection--quite the contrary--to your falling in love elsewhere in the meantime, if opportunity serves."

At this moment Mr. Weil called his companion's attention to a rather corpulent gentleman who had just entered the breakfast room and was stopping near the door to hold a brief conversation with some one he had met there.

"You see that fellow?" he remarked. "Wait a minute, and I will get him over here. If you ever want to put a real character into one of your stories you will only need to take his photograph. In actual life he is as dull as a rusty meat axe, but for literary purposes he would be a godsend."

Catching the eye of the person of whom he was speaking, Mr. Weil motioned to him to come to his part of the room, and as he approached arranged a chair for him invitingly.

"Mr. Boggs, I want to present a young friend of mine to you," said Archie, rising. "Mr. Walker Boggs--Mr. Shirley Roseleaf."

Mr. Boggs went through the usual ceremony, announcing that he was most happy, etc., in the perfunctory style that a million other men follow every day. Then he took the chair that was offered him, and gave an order for his breakfast to a waiter.

"Are you a New Yorker, Mr. Roseleaf?" he asked, when this important matter was disposed of.

"Mr. Roseleaf is staying here for the present," explained Mr. Weil. "He is a novelist by profession, and I tell him there is no better place to study the sensational than this vicinity."

The young man's color deepened. He doubted if it was right to introduce the subject in exactly these terms. Mr. Boggs' next question did not detract from his uneasiness.

"Excuse me--I am not altogether up in current literature, and I must ask what Mr. Roseleaf has written."

Mr. Weil helped his young friend out of this dilemma as well as he could.

"He has written nothing, as yet; at least nothing that has been printed," he said. "He is wise, I think, in laying a deep foundation for his romances, instead of rushing into print with the first thoughts that enter his head, as so many do, to their own subsequent regret and the distress of their readers. I want him to meet men and women who have known what life is by their own experiences. You ought to be worth something to a bright writer, Walker. You have had many an adventure in your day."

Mr. Walker Boggs shrugged his shoulders.

"In my 'day,' yes," he assented. "Enough to fill the Astor and Lenox libraries and leave enough for Charlie Dillingham and The American News Company. But that is nothing but history now. My 'day' is over and it will never return."

He paused and ran his right hand dejectedly across his vest in the vicinity of the waist band. Though he knew perfectly what Mr. Boggs referred to, Archie Weil wanted him to express it in his own words to Shirley.

"You wouldn't think," continued Mr. Boggs, after a pause which seemed filled with strange emotions, "that my figure was once the admiration of every lady who saw it, that they used to stop and gaze at me with eyes of positive envy. And now--look at this!"

He indicated his embonpoint again, and shook his head wrathfully.

"It is simply damnable," he continued, as neither of the others thought best to interrupt him. "When I was twenty-four I had a reputation that was as wide as the continent. When I walked down Broadway you would have supposed a procession was passing,

the crowds gathered in such numbers. If it was mentioned that I would spend a week at Saratoga or Newport, the hotels had not a room to spare while I remained. The next year I married, and as one of the fashion journals put it, two thousand women went into mourning. For a decade I devoted myself entirely to my wife and to business. I made some money, and kept out of the public eye. Then my wife died, and I retired from the firm with which I had been connected. The next twelve months dragged terribly. I did not know what to do. Finally I decided that there was but one course open to me. I must resume again the position I had vacated as a leader of fashion."

Mr. Weil bowed, as if to say that this was a very natural and praiseworthy conclusion; precisely as if he had not heard the story told in substantially the same way a dozen times before. He was watching Roseleaf's interested expression and had difficulty in repressing an inclination to laugh aloud.

"I sought out the best tailor in the city," continued Mr. Boggs. "I went to the most fashionable hair dresser. I spent considerable time in selecting hats, cravats and gloves. When all was ready I took a stroll, as I had done in the old days, from Fiftieth street, down Fifth Avenue and Broadway to Union Square. I met a few acquaintances who stared at me slightly, but did not act in the least impressed. The women merely glanced up and glanced away again. What was the matter? I went home and took a long survey of myself in the mirror, a cheval glass that showed me from crown to toe. My costume was perfect. There was not a wrinkle in my face--this was several years ago, remember. There was not a gray hair in my head then--there are a few now, I admit. 'What is it?' I asked myself a hundred times as I stood there, studying out the cursed problem. My tie was all right, my shirt front of the latest cut, my watch chain straight from Tiffany's, my--ah! I saw it all in a moment!"

Roseleaf, who did not see it even yet, wore such an astonished expression that Mr. Weil had to stuff his napkin into his mouth to prevent an explosion.

"It was this devilish abdomen!" said Mr. Boggs, slapping that portion of his frame as if he had a special grudge against it and would be glad if he could hit it hard enough to bring it to a realizing sense of its turpitude. "My figure had gone to the devil! It was not as large as it is now, but it was large enough to cook my gruel. My waist had increased so gradually that I had never noticed it. I got a tape and took its measure. Forty-two inches, sir! The jig was up. With a heart as young as ever, with a face as good and a purse able to supply all reasonable demands, I was knocked out of the race on the first round by this adipose tissue that no ingenuity could hope to conceal!"

Mr. Weil could wait no longer. His musical laugh rang out over the room.

"Let this be a warning to you, Shirley," he said, "to wear corsets."

"It is no joke," was the indignant comment of Mr. Walker Boggs, as he proceeded to add to his rotundity by devouring the hearty breakfast that the waiter had just brought him. "I am left like a marooned sailor on the sea of life. The only occupation that could have entertained me is gone. It is no time to enter business again, I couldn't have selected a wiser one to leave it. I don't want to marry, once was enough of that. The only women I can attract are those commercially inclined females that any other man could have as well as I. What is the result? My life is ruined. I take no pleasure in anything. I eat, walk about, go to a play, sleep. A _pig_ could do as much; and a pig would not have these memories to haunt him, these recollections of a time so different that I am almost driven wild."

Roseleaf felt a sincere pity for the unfortunate gentleman, and did not see the slightest element of humor in his melancholy recital. But Archie Weil could not be restrained.

"You're right about that pig business," he remarked. "You recall the incident in Mother Goose, where--

'A little pig found a fifty dollar note, And purchased a hat and a very fine coat.'

"There are strange parallels in history."

Mr. Boggs would have replied to this remark in the terms it deserved had he not been too much engaged at the moment in masticating a particularly fine chop. As it was he growled over the meat like a mastiff in bad humor.

"Are there no remedies for excessive accumulation of fat in the abdominal region?" asked Weil, taking his advantage. "It seems to me I have read advertisements of them in the newspapers."

"Remedies!" retorted the other, having swallowed the food and supplemented it with a glass of ale. "There are a thousand, and I have tried them all. I have taken things by the gross. I have paid money to every quack I could find. For awhile I starved myself so nearly to death that I went to making my will. And every day I grew stouter. I don't know what I measure now, and I don't care. A few fathoms more or less, doesn't count, when one falls from a steamer in midocean."

Mr. Weil took occasion to say that there was no need for this extreme discouragement. A little coin in the hand, or a new diamond ring, would still bring youth and beauty to his disconsolate friend.

"That's just it," retorted Boggs. "It's the contrast that's killing me. The only women who would look at me to-day are mercenary ones that wouldn't care if I was black as Othello or big as George IV. Why, I could show you a trunkful of letters, written me by the finest women in this country, when I was at my best. They breathe but one thing--love, love, love! I lived on it! It was the air that kept my lungs in motion. And I thought to go back to it so easily! _Ah!_"

Mr. Boggs commenced upon his fourth chop and emptied the last of the quart bottle into his glass.

"Well, I'm sorry for you," said Weil. "I think the times must have changed, as well as yourself, though. Now, here's a young fellow, with all the qualifications of face, figure and address that you once had, and he claims to be unable to make the acquaintance of a single interesting woman between Brooklyn Bridge and Spuyten Duyvil."

The heavy eyes of Mr. Walker Boggs rested upon the youthful face opposite to him. Under the scrutiny to which he was subjected Roseleaf reddened, in the way he had. He had never looked more handsome.

"This is evidently a jest of yours," said Boggs, turning to Mr. Weil.

"Not in the least, I assure you."

"Then I say he can do what he likes, and I know it," replied the stout man. "If I had his form I'd have to ask the police to clear the way for me. I have seen circulation impeded in front of this very hotel because I was coming out to take my carriage. If he won't look at them, why, of course, the women can't do it all, but it lies with him."

Roseleaf's eyes glistened with a strange mixture of hope and fear. He did not think he would care to be in such great demand as that, but he dearly wished to break through the iron bars that enclosed him. He glanced in a glass that paneled the wall near by. He was good-looking enough, it was no vanity to say so. What he lacked was confidence.

"He is afraid of them, that's his trouble," smiled Weil. "We will cure him of that, and when he gets to know women as they are he will give us a novel that will set all creation by the ears. Gouger--you know Gouger--says he writes the purest English. All he needs is a taste of life."

To this Mr. Boggs gave his unqualified assent. And he added that if he could be of any service in the matter he would only be too glad.

"We thank you for the offer, and may be able later to make use of it," said Mr. Weil. "And now good-morning, for we have important business to attend to."

Roseleaf looked long and earnestly at the person they were leaving. He seemed to him a very ordinary individual. If such a man had won the love of scores of beautiful women, surely he himself could gain the affections of one. When he stood with Weil in front of the hotel, by which an unrivaled procession of ladies and gentleman was already beginning to pass, though it was only eleven o'clock, he felt much encouraged.

"They are looking at you," whispered Archie, "plenty of them. Did you see those two girls in pink in that landau? Why, they nearly broke their necks to get the last glimpse of you. There is another lady who would stop if you asked her, pretty as any of them, though she must be nearly thirty. Your eyes are not open. Ah, here is something better! In that carriage, with the Titian tresses!"

It was Miss Millicent Fern, and she bowed to Mr. Weil. Then her bright eyes lit up with a new lustre as they fell upon his companion.

CHAPTER V.

STUDYING MISS MILLICENT.

When Mr. Weil made his appearance at the residence of Mr. Wilton Fern, the door was opened for him by a young negro of such superb proportions that the caller could not help observing him with admiration. He thought he had never seen a man more perfectly formed. The face, though too dark to suggest the least admixture of Caucasian blood, was well featured. The lips were not thick nor was the nose flat, as is the case with so many of the African race. The voice, as the visitor heard it, was by no means unpleasant. Mr. Weil could not imagine a better model for an ebony statue than this butler, or footman, or whatever position, perhaps both, he might be engaged to fill.

"Yes, sir, Miss Millicent is in, and she is expecting you," said the negro, in his pleasant and strong tones. "Let me take your hat and stick. Now, sir, this way."

Miss Fern came in a few moments to the parlor, where Archie was left, and greeted him most cordially.

"There is a sitting-room on the next floor," she said, "where we shall not be disturbed. I have given Hannibal orders to admit no one, saying that we shall want the evening entirely to ourselves."

"Hannibal?" repeated the visitor. "Is that the name of the remarkable individual who received me just now?"

"Yes," said Miss Fern, rather coldly. "Though I do not know why you call him 'remarkable.'"

"He is so tall, so grand, so entirely overpowering," explained Mr. Weil. "One would think he might be the son of an African king. I never saw a black man that gave me such an impression of force and power."

Millicent elevated her eyebrows a little, as if annoyed at these expressions. She answered, still frigidly, that she had noticed nothing unusual about Hannibal. She did not believe she had looked closely enough at his face to be able to identify him in a court.

"He would make a fine character for a novel," said Mr. Weil, as they walked together up the broad staircase. "I could almost write one myself, around such a personality."

The young lady looked disgusted.

"A negro servant!" she exclaimed. "What kind of a novel could you write with such a central figure?"

"Perhaps I should not put him in the centre," laughed Archie, determined to win her good nature. "Every story needs lights and shades. You can't deny that he would cast a magnificent shadow."

The humor of this observation struck Miss Fern and she joined mildly in her companion's mirth. Then she remarked that the central figure of a novel--the main thing in it--to her mind, should be a being who could be given the attributes of beauty and grace. The minor characters were of less account, and would come into existence almost of their own accord.

"And now, before we do anything more," she said, "I want you to tell me about that excessively handsome young man that I saw with you yesterday in Madison Square."

Weil was delighted at this introduction of his young friend. He began a most flattering account of Shirley Roseleaf, describing him as a genuine paragon among men, both in talent and goodness. He drew heavily on his imagination as he proceeded, feeling that he was "in for it," and might as well do his best at once. And he could see the cheek of the young listener taking on a new and more enticing color as he went farther and farther into his subject.

"If I have to rearrange my novel--the one Mr. Gouger rejected--I shall draw my hero after that model," she cried, when he paused for breath. "I never saw a man who came so near my ideal."

"But--you would have to alter your hero's character, in that case?" he said. "I have read your MSS., and your description does not tally with my young friend at all."

Miss Fern reddened.

"You don't mean to claim, do you," she replied, "that physical beauty and moral goodness always go hand in hand?"

"They should," he answered, in a tone that was meant to be impressive.

"Ah, that is another question! _Do_ they? that is all the novelist needs to know. Did you ever read Ouida's 'Sigma?' There are the two sisters, one as pure as can be, the other quite the opposite, and the beauty belongs to the depraved one. I know Oscar Wilde takes a different view in 'Dorian Grey,' but he is wrong. I am sure that the worst man or woman in the world--reckoning by what are called the 'amiable vices'--might be the most lovely to look upon, the most delightful to associate with. Eve found the serpent attractive, remember."

Where did she learn all these things? Weil looked at her with increasing astonishment. "Amiable vices." He liked the appellation.

"Perhaps you are right," he assented, as if slowly convinced. "If you wish to be acquainted with Mr. Roseleaf, I will bring him here with pleasure. My only fear is that he will not interest you. He seems almost too perfect for earth. Think of a young man who knows nothing of women, who says he has no idea what it is to be in love, who does not understand why the ladies who pass down Fifth Avenue turn their heads to look at him! He, like yourself, is a novelist, but his characters are beautiful images that lack life. He carves marble figures and attempts to palm them off as flesh and blood. He really thinks they _are_, because he has never known the difference. If you could take him, Miss Fern, and teach him what love really is--"

The young lady blushed more than before.

"_I_--" she stammered.

"In a strictly literary way," he explained. "But," he added, thinking he was getting upon the edge of a quicksand, "we must not forget the object of my visit."

He took the parcel containing her MSS. that he had obtained from Mr. Gouger, and began to untie the string. Manlike he soon had it in a hard knot, and Miss Millicent, coming to his rescue, her young hands touched his and made his heart beat faster.

"There," she said, when the knot had given way to their joint endeavors. "It is all right, now. But, before we begin on this, tell me a little more about Mr. Roseleaf. What has he written? Where was it published? I will send to-morrow morning and buy a copy."

Her enthusiasm was agreeable under the circumstances, but the truth had to be explained to her.

"What he has written I will let you see, one of these days," he replied. "As for publishing, he ran upon the same rock that you did--that of Mr. Lawrence Gouger."

The beautiful eyes opened wider.

"So he rejected his work, too! And yet you say that it was well done?"

"Exquisitely. Shirley's lines are as symmetrical as his face and figure. His people are dead, that is all the trouble. Gouger scented the difficulty under which he labors, in a moment. 'Go and fall in love!' he said to him, 'and you will write a story at which the world will marvel!'"

Miss Fern arranged one of her locks of Titian red that had fallen down.

"And hasn't he taken the advice?" she inquired, in a low voice.

"Not yet," smiled the other. "He says, like a very child, that 'he cannot find any one to love.' I walked up the avenue with him to-day, and afterwards rode in the Park. There were hundreds of the prettiest creatures, all looking their eyes out at him. And he hadn't the courage to return one glance, not one. Ah, Miss Fern, it will be genuine love with Shirley Roseleaf, if any. The imitations one finds in the fashionable world will never answer for him."

The young lady breathed a gentle sigh, as her thoughts dwelt on the handsome figure she had seen in front of the Hoffman House.

"You may bring him here--yes, I should be glad to have you," she said, slowly. "But I must ask one favor; do not tell him what I said so thoughtlessly about his being my ideal. Let me talk with him on fair terms. It may be, as you suggest, that we shall be of advantage to each other. When can you arrange it?"

"Almost any day," smiled Weil. "I will let you know, by mail or otherwise. And now, this story of yours," he added, thinking it a shrewd plan to divert her attention from the other matter while it was still warm in her mind. "Though I have read it through, and think I understand it fairly well, I am all the more anxious to hear it from your lips. You will put into the text new meanings, I have no doubt, that have escaped my observation."

Miss Fern flushed pleasantly and inquired with a show of anxiety whether Mr. Weil had found its construction as bad as his friend, Mr. Gouger, had intimated.

"To be perfectly honest, it might be improved," he replied. "But the germ is there, Miss Fern--that necessary thing for a good novel--an interest that will hold the reader in spite of himself. I disagree with Lawrence in his essential point. I am sure that a good writer of English with a taste for fiction could make all the necessary alterations without in the least detracting from the value of the story. For instance, I believe if Mr. Roseleaf would take hold of it I could guarantee to get you a publisher this winter."

"And do you think he would?" she cried.

"I think so."

The authoress was so delighted with this announcement that she conquered the slight wound to her pride. It would be herself still who had drawn the picture, who had put the coloring into it; all that the other would have to do might be described as varnishing. She took up the first sheet of her writing, and turned up an oil lamp that stood upon the table at her elbow, the better to see the lines.

"Are you ready?" she asked.

"Quite ready," smiled Mr. Weil.

In a voice that trembled a little, and yet not unpleasantly to the listener, Miss Fern began to read her manuscript. The opening chapter introduced the heroine and two gentlemen, either one of whom might be the hero. As the book is now so well known it is needless to transfer its features to these pages.

Presently the authoress paused and seemed to wait for her guest's criticism.

"That is one chapter," she said.

"Yes. I remember. And the second one is where Algernon begins to disclose a very little of his true nature. Shall we not have that now?"

"As you like. I thought perhaps you would give me advice as we proceeded, some fault-finding here and there, a suggestion of alterations."

He shook his head affably.

"Not yet," he answered. "Up to this point I see nothing that requires condemnation."

"Nor praise, perhaps?" she said, in a low tone.

"That might be true, also," he replied. "The first chapter of a novel is only the laying of the cloth and the placing of a few dishes. The viands that form the meal are still in the kitchen."

She smiled at the simile.

"But even the laying of the cloth is important," she said.

"Your cloth is laid most admirably," he answered. "And now we will have the castor, which in this case, I believe, contains a certain quantity of mustard and red pepper."

At this she laughed the more, and glanced through a few of the sheets in her hands before she spoke again.

"Did you form any opinion about--about _me_--from this story?" she asked, constrainedly. "Did you, in brief, think it had taken a bold girl to write it?"

He hesitated a moment.

"Yes," he said, at last. "A bold girl, a daring girl, a brave girl. Not one, however, whose own conduct would necessarily be like that of the woman she has delineated."

She was so pleased that she put down the MSS. and leaned toward him with both hands clasped together.

"You are very, very kind," she said, impressively.

"No, merely truthful," he replied. "With your permission I want to retain that last quality in all my conversations with you. When you ask me a question I wish to be perfectly free to answer according to my honest convictions."

"It is what I especially desire," she said, brightening. "No one able to judge has heard anything of this story except your friend, Mr. Gouger. I know it is bold, sometimes I think it is brazen. I can conceive that there are excellent people who would say it never should have been written. To my mind, the moral I have drawn more than justifies the plainness of my speech. You can tell better than I where I have overstepped the proper bounds, if there be such places. You are, of course, a man of the world--"

The protesting expression on the face of her companion arrested her at this point.

"That depends on what you mean by 'a man of the world?'"

"It is a common expression."

"And has many definitions. Before I plead guilty to it, I want to know just how much you intend by it."

Miss Fern put down the page she had taken up and a puzzled look crossed her pretty face.

"You make it hard for me to explain myself," she said. "I suppose I meant--"

"Now, be as honest as you asked me to be," he interrupted.

"Well, then, I suppose you are a man like--like other men."

"But there are many kinds of other men."

The young lady tried several times to make herself clearer, and then asked, with a very pathetic pout, that she might be permitted to proceed with her reading, as the hour was growing later. It was not a very important point, any way, she said.

"I cannot entirely agree with you," replied Archie. "If you are to be a writer of fiction, you should not consider any time wasted which informs you in reference to your fellow creatures. It is from them that you must draw your inspiration; it is their figures you must put, correctly or incorrectly, on your canvas. Don't understand me as dictating to you, my dear Miss Fern. I only wish, as long as you have referred to me, to know of what I am accused."

To this Miss Fern answered, with many pauses, that she had not intended to accuse her visitor of anything. And once more--with evident distress--she begged to be permitted to drop the matter and return to her reading.

"Very well," he assented, thinking he had annoyed her as much as was advisable for the present. "As they say in parliamentary bodies, we will lay the question on the table, from which it can be taken at some more fitting time. I am as anxious as you can be to get into Chapter II."

She read this chapter to the end, and paused a few seconds to see if he had any comments to make, but he shook his head without breaking silence, and she went on with the story. He pursued the same plan till the end of the fifth chapter.

"It is interesting, exciting and true," he remarked, referring to the closing scene. "And I cannot help feeling arise in my brain the question that Mr. Gouger put when he read it: How could a young, innocent girl like you depict that situation with such absolute fidelity."

He had come to the point with a vengeance. But to Miss Fern his manner was far more agreeable than if he had approached it by stealth, or in an insinuating way. She had anticipated something of the sort and had tried to prepare herself to meet it.

"Does not nature teach us some things?" she asked, speaking straightforwardly, though her color heightened in spite of her efforts. "Given a certain condition, an intelligent mind can prophesy results."

He shook his head in mild disagreement with her.

"Gouger is an expert, and he denies this, as a regular rule, at least. You should have heard him argue it with Roseleaf. 'Either throw yourself into a love affair,' he said, 'or never try to depict one.' Excuse me, Miss Fern, you bade me be frank--"

She assented, with a grave nod of her shapely head.

"You may have been in love--I do not ask you whether you have or not--but you cannot have known personally of the sort of love that you have depicted in these pages. I call it little less than miraculous that you should draw the scene so accurately."

She colored again, this time partly with pleasure, for she was very susceptible to compliments.

"Perhaps your statement may explain to you," she said, pointedly, "what I meant a few minutes ago by calling you 'a man of the world.' You recognize at a glance what I had to construct from my imagination."

Archie Weil's face changed as he realized how deftly he had been caught. He had meant to pretend to this girl that he was more than usually ignorant of the nether side of life.

"Don't think too badly of me because I happen to know what is clear to every man," he said, impressively.

"To every one?" she answered. "To your friend, Mr. Roseleaf?"

"Ah! He is an exception to all rules. And yet, Gouger says he can never write a successful book till he is more conversant with life than he is at present."

She looked troubled.

"With life?" she echoed. "With sin, do you mean?"

"With the ordinary things that men know, and that most of them at some time experience."

Her bright eyes were temporarily clouded.

"What a pity!" she exclaimed.

"Yes," he said, for it was his humor to agree with her. "It is a pity."

There was a pause of a minute, and then she asked if she had read enough for one evening. He answered that as it was now past ten o'clock it would not be easy to get much farther and that he would come again whenever she chose to set the time.

"You do not say much about my work," she said, anxiously, as he prepared to go.

"Silence is approval," he responded. "I can talk it over with you better when you have reached the end. I have things to say, and I shall not hesitate to say them then."

"When is it most convenient to you to come?" she inquired.

"Any time," he answered. "I don't do much that is really useful. But wait till you see Shirley. He will atone for the shortcomings you find in me."

She repeated the word "Shirley," as if to test its sound.

"You are your father's only child, are you not?" he asked, thoughtfully.

"No. I have a sister, Daisy, a little younger than I."

"And has she a literary turn, also?"

"Not in the least."

Archie arose, and Miss Millicent accompanied him to the front door. The tall negro came to open the portal, but Miss Fern told him, with the same quality of dislike in her tone which Weil had noticed before, that he need not wait.

"He is really a magnificent piece of humanity," said Archie, when the man had disappeared. "I never saw anything quite like him."

"You admire negroes, then?" said the young lady, almost impolitely.
